Introduction

Polymers or so-called macromolecules are known as large molecular structures that contain one or more units, which are repeated within the molecule. The term 'polymer' has its origin in Greek and is derived from the term 'poly' that means many and 'mer' meaning unit. Polymers are usually prepared by a reaction between identical or similar molecules in order to produce a theoretically infinite chain. In reality, reactions usually result in a range of long chains as they are hindered by molecular motions and side reactions. Biopolymers stand among the kinds of polymers, which are generated through the means of living organisms and can be acknowledged as polymeric biomolecules. The term "Biopolymer" stands for a biodegradable polymer, which is recognized as a biodegradable chemical compound and considered the most organic composite throughout the ecosphere. All of the existing biopolymers (DNA, proteins, carbohydrates, lipids, polysaccharides, polyphenols, and nucleic acids) hold a great portion of the human body and ecosphere. Since the whole structure of body and genetic behaviors that is transported from parents to children is based upon DNA biopolymer, they are quite significant for mankind. Representing the most frequently utilized biopolymer, Cellulose contains the greatest abundance as an organic compound on earth, which consists 33% of all the plant components on this particular planet. One of the objectives of biology has been the production of polymers for as long as life has existed. Biopolymers form the basis of genetic encoding, cell structures, and extracellular matrices, while their biodegradability is evident throughout the cycle of life. Among these polymers, the two main classes that are employed nowadays are proteins and polysaccharides. Silk and cotton are excellent examples of biodegradable natural polymers that are used on daily basis. Silk is a protein-based material whereas cotton is known as a polysaccharide-based material and they have been both utilized by humans for millennia to cause great effects. The existing interest in these materials is due to their relative stability in abiotic hydrolysis when compared to relatively rapid biotic degradation. The genesis of biopolymers can be performed by using renewable sources while their biodegradable procedure can be easily achieved due to the presence of oxygen and nitrogen atoms throughout their structural backbone. Biodegradation can alter biopolymers into CO₂, water, biomass, humide matter, and other natural substances, which indicates that they are capable of being naturally recycled through the means of biological methods.

Considering how nanoparticles accommodate specific physicochemical qualities and practical attributes, their utilization as ingredients in food industry is notably expanding. The utilitarian operation of biopolymer particles can be changed by their various dimensions. To be stated as an example, the effects of particle size has been observed on the bulk physicochemical qualities of foods (Optics, rheology, and stability), encapsulation characteristics (e.g., loading, retention, and release), and behavior throughout the gastrointestinal tract (GIT; e.g., transport, degradation, interactions, and penetration). In addition, the significance of surface molecules over the bulk molecules can be intensified by the high ratio of surface/volume that seems to cause an impression on the induced phenomena at the interfaces, such as oxidation or digestion (Matalanis *et al.*, 2012; Li *et al.*, 2011). We have distinguished the data in correlation with the employed monomeric unit and the structure of produced biopolymer (Table 1) (Kaewkannetra, 2012).

The United States Congress Office of Technology Assessment has categorized them into five groups (Ramesh *et al.*, 2010) as the following:

- Nucleic acids
- Proteins
- Polysaccharides
- Polyhydroxyalkanoates
- Polyphenols

Biopolymer can be also distinguished (Table 2) (Yadav *et al.*, 2015) as the following by considering their origins:

Table 1 Classification of biopolymers in accordance with the utilized monomeric unit and structure

Classification	Description
Polynucleotides	DNA and RNA which are long polymers composed of 13 or more nucleotide monomers
Polypeptides	Short polymers of amino acids
Polysaccharides	Linear, bonded polymeric carbohydrate structures

Table 2 Classification of biopolymer based on their origin

Type	Example
Polyesters	Polyhydroxyalkanoates, Polylactic Acid
Proteins	Silk, Collagen, Elastin, Resilin, Adhesive, Polyaminoacid, Soy, Zein, Wheat Gluten, Casein, Serum Albumin
Polysaccharides	Plant/Alga Starch, Cellulose, Agar, Alginate, Carrageenan, Pectin, Konjan, Various Gums Animal Chitin, Hyaluronic Acid, ... Bacterial Xanthan, Dextran, Gellan, Levan, Curd Lan, Polygalactosamine, Cellulose Fungal Pollulan, Elsinan, Yeast Glucans
Lipids/Surfactants	Acetoglycerides, Waxes, Emulsion
Polyphenols	Lignin, Tannin, Humic Acid
Specialty Polymers	Shellac, Poly Gamma Glutamic Acid, Natural Rubber, and Synthetic Polymers from Natural Fats and Oils

**Fig. 1** Structure of sucrose showing the glycoside bonds.

Sources and Structure of Some Natural Polymers

All of the existing proteins can be classified as biodegradable. The cycle of life relies on the ability of breaking down and reusing the amino acids of proteins in order to construct cells, enzymes, and many other building blocks of complex organisms. Their structures are commonly complex, not just in their chemical make-up, but also throughout their exact structure. The process of folding and coiling proteins into specific geometries can influence their properties and functionalities. At elevated temperatures, the thermal disruption of these complex structures usually results in spelling the end of life for most organisms. The degradation procedure of proteins is dependent on some specific enzymes, while the simple chemical degradation seems to be generally slow without enzyme intervention. Throughout this particular section, we aim to briefly discuss the chemistry and properties of some natural polymers.

Polysaccharides

Polysaccharides are capable of forming a massive class of natural polymers, which are often modified before being utilized. They can compose some of the first polymeric materials that are used by humans for manufacturing applications, along with nitro-cellulose which was once employed for the production of films and gun cottons. The polysaccharide class of natural polymers is based upon polymers with repeat units which are founded by sugars. The sugar repeat units that exist on the backbone of polysaccharides contains many chiral centers that determine the exact saccharide. For example, all of the available saccharides carry the same nominal formula, $C_6H_{12}O_6$; however, each one is distinctly different due to their particular chiral nature. Within a polysaccharide, the saccharide repeat units are apparently connected via the oxygen of carbon 1, which forms a glycosidic bond with carbon 4 in another molecule, subsequent to the elimination of water. Fig. 1 illustrates an example of this process, while the source structure can be also observed.

Cellulose

There is a large number of polysaccharides that are being employed as degradable polymers, while cellulose (Fig. 2) probably stands as the most commonly utilized, which is the general component of cotton. This substance is acknowledged as a significant and captivating biopolymer and contains an exceptional position throughout daily life and industrial applications since next to

Fig. 2 Molecular structure of Cellulose.

Fig. 3 Molecular structure of Starch.

being a sustainable natural raw material, it is almost impossible to exhaust cellulose. It should be mentioned that this particular substance is a promising pyrolysis precursor for providing carbon's species (Ruan *et al.*, 2018), which can be discovered within the cell walls of superior plants. Cellulose accommodates various favorable qualities, including mechanical robustness, hydrophilicity, biocompatibility, biodegradability, relative thermostability, high sorption capacity, and alterable optical appearance, and is known to be the most plentiful and copious biomass material that nature has to offer (Hu *et al.*, 2014).

The alteration process of a polymer usually involves the modification of OH groups that exist on the backbone of the designated polymer by the utilization of an acid anhydride. The performance of this sequence can result in various degrees of substitution in order to obtain ester functionalized celluloses (Edgar *et al.*, 2001). It must be noted that similar modifications have been attempted with other polysaccharides as well (Campoccia *et al.*, 1998). Although the amazing features of cellulose have given it the potential to be employed throughout a wild range of fields, yet from the Approximately 5×10^{11} metric tons of this substance that is produced yearly, only 2% is apparently recovered industrially (Qiu and Hu, 2013).

Other polysaccharides that build the different parts of this group of degradable polymers include starch, larch gum, alginic acid, agar, carrageenan, chitin, hyaluronic acid, dextran, gellan gum, and pullulan. Most of these polysaccharides structures are complex and a full discussion on their topic is available in the literature (Mano *et al.*, 2007). Among the mentioned substances, starch, cellulose and larch gum are plant derived (although cellulose may also be obtained from microbial sources), while alginic acid, agar, and carrageenan are commonly obtained from algae, chitin and hyaluronic acid are procured from animal sources or microbial sources, and the others are achieved from microbes.

Starch

Being formulated by linear amylose and branched amylopectin chain (Fig. 3), starch is known to be a genuinely plentiful polymeric carbohydrate (Finkenstadt and Willett, 2004).

The available semi-crystalline starch granules can be altered into an amorphous state through the utilization of gelatinization method (Ai and Jane, 2015). The observation of water molecules that seemed to be tightly and loosely bounded as an effect of the starch chain network throughout the procedure has been quiet fascinating, which can force reasonable ionic conductivity out of starch and label it as a solid polymer electrolytes (SPEs) (Shukur *et al.*, 2014; Liew and Ramesh, 2015; Raeis-Hosseini and Lee, 2016). The origin qualities of starch need to be improved for the purpose of achieving practical materials, since this substance contains high water sensitivity and poor mechanical features when it is contrasted with those of synthetic polymers (Mourya *et al.*, 2010). Starch and biopolymer have been chemically modified in synthetic polymers (Mohanty *et al.*, 2000). Plants such as potato, rice, maize (corn), and cassava are the utilized raw materials for the production of biopolymers. The main component of these specific plants is starch, which is capable of being employed in biodegradable materials due to being cheap, available, and

produced from renewable resources. Starch is known to be the mixture of two D-glucan homo polymers, is composed of α -D-glucopyranosyl units (AGU) that includes amylose and amylopectin. The molecular weight of amylose relies on the starch origin (Patil, 2010), which generally contains a lower molecular weight if it has been extracted from cereals. Considering its abundant and being a polysaccharide that is naturally induced, starch has been commonly utilized for the preparation and evaluation of edible biodegradable films (Tuil *et al.*, 2000).

Chitin

poly (-(1-4)-N-acetyl-D-glucosamine) that is acknowledged as chitin has been initially discovered in 1884 and recognized as a significant and vital natural polysaccharide. The synthesizing process of this particular biopolymer is achieved by the employment of a vast number of living organisms, while this substance has occupied the second position after cellulose in regards to the portion of its annual production as well as its abundance as a polymer. Chitin is generally perceived throughout the nature in the shape of ordered crystalline microfibrils that produce structural components within the exoskeleton of arthropods or cell walls of fungi and yeast. It can be also composed through different other living organisms that exist in the fields of lower plant and animal kingdoms and diversely operate upon the requirement of reinforcement and strength. Chitosan stands as the most notable derivative of chitin, which is procured either through the application of (partial) deacetylation of chitin within the solid state and under alkaline circumstances (concentrated NaOH) or by enzymatic hydrolysis in the appearance of chitin deacetylase. The achieved chitosan by the means of solid-state reaction seem to contain a heterogeneous distribution of acetyl groups along the chains, which is apparently caused by the semi-crystalline morphology of chitin. Chitin and chitosan have proved to be biocompatible, biodegradable, and non-toxic polymers (Jayakumar *et al.*, 2010).

Proteins

Considering how proteins can be applied for enhancing new blend and/or composite materials, they seem to be more practical than the other natural polymers. The structural form of proteins has been observed to be either globular or fibrous when they are stabled in their natural state. A sphere-shaped structure has been perceived in globular folded proteins, which are held mutually through the existing disposition of hydrogen, ionic, hydrophobic, and covalent (disulfide) bonds. On the other hand, the structure of fibrous proteins seems to be completely extended and coupled quiet strongly together in the form of parallel constructions, which are generally induced by the means of hydrogen bonds for the purpose of developing fibers. The chemical and physical qualities of these specific proteins apparently rely on the comparative portion of amino acid resultants, along with their position next to the polypeptide chain. The chemistry and science of polymers can be improved by the utilization of amino acid sequence and other organic and synthetic polymers. Moreover, this assessment can be more profiting if there are adjustments in chemical and protein engineering in order to obtain a novel design of polymers from proteins. Several scientists have performed investigations on the blends of protein with nonprotein, natural, and synthetic molecules including keratin-chitosan (Tanabe *et al.*, 2002), glutenmethyl-cellulose (Zuo *et al.*, 2009), keratin-polypropylene, keratin-cellulosepolypropylene (Bullions *et al.*, 2003, 2004; Schuster, 2000), and keratin-polyethylene (Barone and Schmidt, 2005) etc., and it has been suggested from their observations that the features of native protein film has been enhanced to some extend (i.e., film strength, flexibility, and water vapor permeability, etc.). The application of gluten (Mojumdar *et al.*, 2011), milk protein (Ramos *et al.*, 2013; Bahram *et al.*, 2014), and soy protein (Su *et al.*, 2010) has been employed for the production of edible film, while keratin implementation for the growth of nanofiber (Aluigi *et al.*, 2008), film (Barone *et al.*, 2005), and composites (Bertini *et al.*, 2013) in the field of material industries has been evident. Protein based natural polymers are intensely getting involved throughout the various fields of biomaterials (Xing *et al.*, 2011), packaging material, and coatings industries (Scheller and Conrad, 2005). Throughout the present article, we have facilitated the featured of protein within its native state in regards to the genesis of bio-based polymer and polymer reinforcement methods in order to upgrade the characteristic/qualities of peptide polymer, which will probably lead to novel designs of polymers. An inclusive analysis has been presented in regards to the implementation of mentioned protein blends and composites, which are ranging from micro to macro structural level.

Silk

Silk is known as a protein that is based upon the large extent of the fragment Gly-Ala-Gly-Ala-Gly-[Ser-Gly-(Ala-Gly) n]8-Ser-Gly-Ala-Ala-Gly-Try (Lucas *et al.*, 1962). This specific substance has caught the attention of many due to its high tensile strength and excellent mechanical properties. The high performance of silk is thought to be a result of the large numbers of ordered sheets that is caused by the folding of proteins. Silk itself is obtained from the cocoons of mulberry silkworm (*Bombyx mori*) and is generally procured by unravelling the fibers that enwrap the cocoon. Nowadays, the larvae themselves are particularly farmed. The ease of obtaining silk with little processing has explained its prevalence since ancient times.

Collagen

The quaternary structure of collagen is acknowledged to be composed of three lefthanded helices that are deformed into a right-handed coil. Collagen is formed by a cluster of naturally induced proteins that can be discovered within animals and due to its un ordinary features including biodegradability and weak antigenicity (Lee *et al.*, 2001), it has been labeled as a significant biomaterials in regards to tissue engineering implementations. The fibers of collagen are generally observed to be a white, opaque, and viscoelastic matter, which

usually demand a high tensile strength along with less extensibility. This specific material contains the role of biomaterial throughout the fields of drug delivery systems (Friess, 1998) and tissue engineering (Pachence, 1996). In accordance with the analysis of a scientist, the Young's modulus of the rat tail collagen Type I seem to vary between 3.7 and 11.5 GPa (Wenger *et al.*, 2007). In order to be utilized for fabricating practical biomaterials that can be employed in clinical application, a sequence of investigations has been targeted on the structural and tensile qualities of collagen scaffolds (Chen *et al.*, 1995; Matsuda *et al.*, 1993; Yannas and Burke, 1980).

Keratin

Being the kind of a protein that holds bonds of disulfide, Keratin contains an array of features that varies from a structurally robust, impact-resistant substance (horn) towards an uncomplicated waterproof layer (turtle shell). It is known that this material is mechanically functional in both tension (wool) and compression (hooves) circumstances (Feughelman, 1959). Keratins can be discovered within hair, wool, claws, nails, skin, fur, hooves, beaks, feathers, horns, scales, and actin, while the myosin protein is commonly observed in muscle tissues. The difference in content of sulfur is the principal reason behind the existence of various keratins. The appearance of lots of cysteine disulfide crosslinks will result in decreased flexibility, as it can be perceived in claws, hooves, horns, and nails, while in regards to textures such as wool, skin, and muscle proteins, there are apparently less disulfide crosslinks and although a bit of stretching is possible, yet it will return to the normal position as the tension is reduced.

Synthetic Biopolymers

Unlike natural polymers, degradable synthetic polymers may be readily mass produced on a multi-ton scale and contain properties that are similar to nondegradable polymers. There is a vast range of degradable polymers and many others are being discovered and appended to this list on a daily basis; however, they may be divided into several classes since each one can contain specific properties. The properties of a degradable polymer depend on the ability in its manufacturing procedure and its components without significant degradation, as well as accommodating a suitable lifetime for the final material to fulfill its role. The challenge of balancing these factors has driven continued research towards this area. Moreover, the wide range of applications for degradable polymers usually dictates the type of polymer that is required to be used. To be stated as an example, a degradable polymer for human implant, which functions as a slow release mechanism, must not degrade into toxic or irritating components that could cause an inflammatory response. There are three main classes of degradable synthetic polymer, including polyesters, polycarbonates, and polyanhydrides, and in addition to these, a different range of polymers exists that involves other degradable groups including amino acids and phosphates.

Polyesters

Polyesters contain the ester linkage between monomer units. This type of bond is usually, but not exclusively, formed via either a trans-esterification reaction or a ring opening reaction. There are five main polyesters which are considered to be biodegradable: polyglycolic acid (PGA), polylactic acid (PLA), poly-*ε*-caprolactone (PCL), polyhydroxybutyrate (PHB) and polyhydroxyvalerate (PHV). PGA, PLA and PCL are all readily prepared via ring-opening polymerizations (Labet and Thielemans, 2009). Typically, polymers are composed in the molten monomer by using a catalyst (octanoate) for the purpose of promoting the ring opening process. Tin octanoate is known as a traditional catalyst and due to the hazards of its usage and associated toxicity, there have been several other catalysts developed over the recent years, whereas in this respect, the production of catalysts for controlling the chiral centers in PLA has been of particular interest (Thomas, 2010).

Polycarbonates

Polycarbonates are a similar class of polymer to polyesters and can be prepared through a similar ring opening polymerization process to that of the mentioned polyesters (Rokicki, 2000). The examples of polycarbonate-based degradable polymers have been restricted within the main to poly (trimethylene) carbonate.

Polyanhydrides

The polyanhydrides are perhaps some of the least hydrolytically stable degradable polymers. There are many examples that hold the anhydride group as part of their repeat unit. Poly(1,3-bis-*p*-carboxypheloxypropane anhydride) is probably one of the best representatives of the degradable polyanhydrides that are currently being utilized (Kumar *et al.*, 2002), as well as being generally prepared by the means of condensation reactions.

Biopolymer Nanofibrils

Biopolymer nanofibrils stand as the universal nano-building blocks throughout the field of natural materials (Neville, 1993; Meyers and Chen, 2014; Naleway *et al.*, 2015), such as cellulose nanofibrils (CNFs) that exist within plants and bacteria, chitin nanofibrils (ChNFs) in animals, and silk nanofibrils (SNFs) existing in spider and silkworm cocoon silks, as well as collagen nanofibrils (CoNFs) that can be discovered in ligaments, mammalian tendons, and bones. Being constructed from various biopolymer molecules, biopolymer nanofibrils

seem to contain different chemical reactivities such as cellulose, chitin, silk fibroin, and collagen; nevertheless, at higher structural levels they apparently possess similar properties. In addition, CNFs, ChNFs, SNFs, and CoNFs represent the four most plentiful biopolymer nanomaterials that nature has to offer and considering how they contain fascinating mechanical qualities, wide-availability, sustainability, biocompatibility and biodegradability (ChNFs, SNFs, and CoNFs), many scientific and commercial interests have been focused on these materials over the past years (Xiong *et al.*, 2018; Chen *et al.*, 2018; Kumar, 2000). Nonetheless, it is of great value to perform qualified investigations on these particular biopolymer nanofibrils since beside being the most plentiful among their kind on earth, they also stand as the four prototypes that have demonstrated the nature capability in producing similar constructions with the utilization of different elements (Ling *et al.*, 2018). A sequence of top-down and bottom-up tactics have been arranged and done for the purpose of procuring biopolymer nanofibrils. Considering the prospects of biopolymer nanofibril implementations, CNFs, ChNFs, SNFs and CoNFs seem to accommodate various significant and typical characteristics that rise from their nano-size influences, which involves ultra-high specific surface areas and length to diameter ratios (Liu *et al.*, 2014; Wu *et al.*, 2016), nanoporous structure (Ling *et al.*, 2016, 2017), nano-confinement effects (Giesa *et al.*, 2014), and optical transparency (Ling *et al.*, 2014). The existence of these specific features that are quiet common in biopolymer nanofibrils has created the possibility of inventing and employing these substances in similar procedures.

Cellulose Nanofibrils

Nanocellulose is known to be the most plentiful biopolymer nanomaterial that can be discovered in the living world (Moon *et al.*, 2011), which is commonly formed through plants, marine animals, algae, fungi, and amoeba. The functionality of CNFs in most of the existing organisms is to be the structural components within the cell walls. We can distinguish and place Nanocellulose in the group of cellulose nanocrystals (CNCs) and CNFs, which would be in correlation with their morphology. CNFs can be alluded to nanofibrils that hold long lengths and high aspect ratios and on the other hand, the nanofibrils that accommodate high crystallinity and relative shorter lengths along with lower aspect ratios are acknowledged as CNCs or cellulose nanowhiskers. In addition, the expression of cellulose nano-objects has been utilized for describing both CNFs and CNCs. Being directed to nanostructured cellulose that are generated by bacteria, bacterial cellulose (BC) is recognized as another kind of CNFs (Wu *et al.*, 2015). Four various crystalline conditions have been perceived for cellulose, cellulose I, II, III, and IV, which promotes dissimilarities upon the position of hydrogen bonds between and within strands. Being interpreted as the native nanocrystal structure, cellulose I contains two allomorphs, i.e., I α and I β . The I α crystalline seem to have bacteria and algae under its influence, while the I β crystalline is apparently abundant in plants (Oehme *et al.*, 2015). Being the principal element of wood, crystalline cellulose is the key factor in figuring the stiffness and strength of a wood. This particular substance has not been observed to exist alone within most of the biological material throughout the nature, but congregates with various kinds of organic materials for the purpose of shaping composites. To be stated as an example, CNFs can be discerned in the wrappings of soft matrixes that are formulated by hemicellulose and lignin within wood (being the most plentiful resources of cellulose). The vast employment of CNFs for developing optoelectronic, energy, and environmental devices throughout scientific and commercial fields has been quite evident. The global manufacturing capacity of nanocellulose (involving CNFs and CNCs) has been approximately on the order of 600 metric tonnes/year throughout 2013, while the capability of future global market has been estimated to be 35 million metric tonnes/year (Arvidsson *et al.*, 2015). The evolution of many innovative CNF/CNC-based nano-composites have been arranged upon the different methods of coordination hybridizing (Saito *et al.*, 2014; Hamed *et al.*, 2014; Malho *et al.*, 2015). A flexible procedure for the production of polymer nano-composites has been invented, which involves the application of tunicate CNCs as its building blocks (Capadona *et al.*, 2007). Additionally, CNFs are known to be fascinating raw materials for the construction of practical aerogels/foams as well (Svagan *et al.*, 2008; Kettunen *et al.*, 2011; Khan *et al.*, 2016; Tian *et al.*, 2015a). In order to produce magnetic aerogels, freeze dried BC aerogels have been employed in the role of templates that were further compacted to turn into a stiff magnetic nanopaper (Olsson *et al.*, 2010). The slender size (smaller than the wavelength of visible light) along with high mechanical- thermal- performances can be considered as some of the rare features of CNFs that can finance its auspicious implementations throughout the optical fields. It has been proved that the CNF-based optical materials can accommodate high optical transparency, superb flexibility, and reduced thermal expansion. Although CNFs are not capable of conducting electricity on their own, yet their combination with other electrically conductive substances can be well situated for establishing electronic materials. By the application of vacuum filtration, different conductive materials have been formed and deposited on the CNF-derived nano-papers, which includes silver nano-wires, graphene, and carbon nanotubes (CNTs) (Koga *et al.*, 2014; Yan *et al.*, 2014). As there are many requests for CNFs in regards to the electronic devices, it must be noted that a combination with functional electrochemistry substances is needed for the utilization of CNFs in energy-related applications, such as graphene (Zheng *et al.*, 2017; Gao *et al.*, 2013) and conductive polymers (Wang *et al.*, 2015, 2013). Recently, the assessment of CNF-based substances throughout the field of solar cells is becoming quiet apparent (Zhou *et al.*, 2013; Nogi *et al.*, 2015). An intensifying light absorption within the active layer can be caused by CNF nano-papers, since they contain large forward light scattering that can extend the length of light path (Hu *et al.*, 2013). CNF films can be employed without being altered as filtration membranes throughout the relative procedures of environmentally-related purification, due to their intertwined and packed CNF networks. The usage of CNF membranes for the task of filtering nanoparticles (including inorganic nanoparticles, bacteria, and viruses) has been determined due to their size exclusion, considering how CNF membranes contain smaller pore sizes in comparison to most of the other nanoparticles (Metreveli *et al.*, 2014).

Chitin Nanofibrils (ChNFs)

Being a derivative of glucose in chemical terms, chitin can be generally acknowledged as a cellulose analog –, which is a long-chain polymer of (1,4)- β -N-acetylglucosamine (Fig. 1) (Ogawa *et al.*, 2016). The advantageous features of chitin has been preserved by ChNFs while demonstrating a fascinating biocompatibility, biodegradability, reduced immunogenicity, and antibacterial functionality, which is quite different from CNF-based materials that are fabricated from top-down approaches and commonly result in deficient biocompatibility and biodegradability (Jayakumar *et al.*, 2010; Muzzarelli, 2011; Anitha *et al.*, 2014; Rinaudo, 2006). The appealing chemical, morphological, and mechanical benefits of ChNFs have been evident throughout their implementations in the field of tissue engineering (Islam *et al.*, 2017; Kiroshka *et al.*, 2017). Moreover, for the enhancement of strength and cell adhesion of the designated materials, ChNFs have been merged with different synthetic polymers and biopolymers, including polyglycolide, polycaprolactone, polylactic acid, collagen, cellulose, silk, and chitosan (Siró and Plackett, 2010; Fernandez *et al.*, 2005). It is apparent that the deacetylated ChNFs have advanced the proliferating process of fibroblasts that has led to the creation of proliferation and re-modeling phases throughout the procedure of wound healing (Izumi *et al.*, 2015). In contrast to the mentioned fact, chitosan is known to be a little bit soluble within acidic aqueous media and as a derivative of chitin, it has the potential to turn into nanofibrils if certain circumstances are facilitated (Ding *et al.*, 2014). Functioning as a substrate has been another application of CNFs for the purpose of keeping the companion of other components, such as gold nanoparticles, which results in the manufacturing of biosensors (Gomathi *et al.*, 2011). Considering its position as the most plentiful natural nitrogen-containing biomacromolecule, chitin has the capability of being modified into N-doped carbon-based materials and utilized in the role of electrocatalysts for the reactions of oxygen reduction (Borghei *et al.*, 2018). In accordance with the reported observations, Chitosan nanofibril-based materials are capable of displaying fascinating features in adsorbing multiple cations, anions, and radionuclides within air and aquatic habitat pollutants (Bhatnagar and Sillanpää, 2009; Jiuhui, 2008; Haider and Park, 2009).

Silk Nanofibrils (SNFs)

SNFs stand as the most essential nano-elements within the structures of spider and silkworm cocoon silk fibers, which have been perceived to contain some similar constructional characteristics in various species. To be stated as an example, a beaded topological construction has been promoted by all of the single SNFs, which are apparently linked by homogeneous nano-globules that have a diameter fluctuation within the range of 3–5 nm. In the cases of spiders and silkworm cocoon silks, these particular nanofibrils can be bundled into 20–200 nm thick fibrils (Also expressed as microfibrils) and be further processed to turn into silk fibroin filaments (Nguyen *et al.*, 2015). With regards to the appealing features of Silk fibroin, which include biocompatibility, tunable biodegradability, and adaptable processability, a great amount of investigation has been performed on this topic in biomedical fields (Vepari and Kaplan, 2007). Nevertheless, it must be noted that in comparison with silk fibroin, SNFs have shown more different properties for biomedical implementations. Generally, SNF hydrogels and scaffolds can be discovered within hierarchical micro- and nanoporous constructions, which have proved to be beneficial in regards to cell adhesion/migration and nutrient transmission (Liu *et al.*, 2014). It has been suggested by some of the past reports that in order to achieve the effects of nano-size and high specific surface area of single nanofibrils, the pore size of SNF elements should be adjusted towards the range of designated nanometer scale (Ling *et al.*, 2017, 2014). The biominerals (e.g., calcium carbonate (Bai *et al.*, 2014) and hydroxyapatite nanocrystals (Mi *et al.*, 2016)) or inorganic nanomaterials (e.g., silver and gold nanoparticles (Dong and Lu, 2014; Lv *et al.*, 2017)), which had been fabricated through the course of the procedure, seemed to be confined in the networks of SNF and therefore ended up in a stabilized situation in the form of a suspension within the solution.

Collagen Nanofibrils (CoNFs)

Collagen contains the largest quantity of protein that exists in the body of mammals, which is approximately 25%–35% of their protein content (Di Lullo *et al.*, 2001). Until now, Type I, II, III, IV, and V stand as the most general kinds of collagen in between the 28 types that have been discovered, while type I, II, III, V, and XI are known to be built of fibrillar constructions (Cen *et al.*, 2008). Consisting 90% of all the existing collagen in the body, type I collagen has been identified as the principal collagen that can be observed in bones, tendons, corneas, and ligaments (Di Lullo *et al.*, 2001). CoNFs have caught the attention and interest of many, especially for biomedical implementations, due to containing fascinating biological qualities that include high biocompatibility, biodegradability, and weak antigenicity (Lode *et al.*, 2016; Shen *et al.*, 2014). In regards to biomedical applications, CoNFs have been utilized in massive quantities for cartilage repair, considering how the existence of non-vascularized tissues results in reducing the potential of cartilage for intrinsic regeneration and thus, cause this procedure to be quiet challenging (Rosenzweig *et al.*, 2017; Lode *et al.*, 2016). The compatibility of CoNFs with a series of biopolymers and inorganic materials, such as chitin/chitosan, (Shen *et al.*, 2014), silk fibroin (Vepari and Kaplan, 2007), silver nanoparticles (Srivatsan *et al.*, 2015), minerals (Maté-Sánchez de Val *et al.*, 2014), ceramics (Brodie *et al.*, 2005) have been approved, while this harmony can be further processed into versatile composites in order to fulfill the necessities of their applications throughout blood vessels, heart valves, and nervous and bone tissue engineering. On account of their unique hemostatic and antibacterial features, low antigenicity, and biocompatibility, the application of CoNFs can be considered for composing mechanically robust and biodegradable materials, which can be utilized for wound sutures and reconstructive surgeries (Maffia *et al.*, 2004; Huang *et al.*, 2009). Next to being beneficial throughout the treatment of idiopathic pulmonary fibrosis immunotherapy (Wilkes *et al.*, 2015), arthritis, and rheumatoid

arthritis (Woo *et al.*, 2017), collagen has been recognized as a natural nutrient (a cholesterol-lowering food) (Sun *et al.*, 2011) that is capable of performing a well-organized dermal matrix synthesis. Regarding the application of CoNFs in food industry, this substance is commonly provided as edible meat casings, binders, emulsifiers and extenders in sausages and hams, next to being employed in the role of additives for advancing the capacity of water holding and enriching the tastes of meats (Schilling *et al.*, 2003). The health of humans has been severely threatened by the effects of induced amassing within the living organisms, which is caused by environmental contamination and specifically heavy metal ion pollutants (Maffia *et al.*, 2004), while as it has been previously noted, most of the discovered ultrafiltration membranes and adsorbents are either incompetent or can only partially discard and eliminate the heavy metal ions of contaminated solutions. The vast utilization of CoNFs for the production of heavy metal ion adsorptive materials has been quiet evident throughout the past decade (Huang *et al.*, 2009; Sun *et al.*, 2011). Additionally, this substance is capable of displaying integrating behaviors with other materials for water treatment purposes, which is similar to the features of CNFs, ChNFs, and SNFs; some of the examples of this procedure would be the processing of CoNFs into composite systems with Zr (IV) to obtain fluoride adsorption (Liao and Shi, 2005), Fe(III) and Al(III) to discard and eliminate phosphate (Huang *et al.*, 2009), and tannins to achieve uranium adsorption (Liao *et al.*, 2004).

Application of Biopolymer in the Synthesis of Nano-Structures

In accordance with the available data, there are lots of metal and metal oxide nanoparticles that are capable of functioning as sorbents, catalysts, sensors, reducing agents, and bactericides due to their rare and specific qualities (Yazdi *et al.*, 2018a,b; Charbgoor *et al.*, 2017; Hasanazadeh *et al.*, 2018; Khorrami *et al.*, 2018; Moghaddasi *et al.*, 2018). Although these particular nanoparticles can provide fast kinetics and improved sorption capacity because of their high surface to volume ratio, yet the existing disadvantages, including propensity to aggregation, exceeding reduction of high pressure in the course of flow-through systems, the absence of specificity throughout reactions in complex systems, and deficient mechanical strength, have usually terminated their chances of constant real-life applications. Acknowledged as a whole different kind of organic materials, functionalized polymers and biopolymers have been approved of being robust, chemically stable, and amenable to chemical adjustments, which are dependent on the requirements of the designated implementation. The sudden progress of these synthetic and semi-synthetic functionalized materials, which are in many cases expressed as reactive polymers or ion exchangers, can be clearly perceived throughout the course of the last five decades by their existing reports of multitude scientific attempts that varies from mining to microelectronics, deionization to decontamination, synthesis to sensing, drug delivery to desalination, and etc (Zagorodni, 2006). This project aims to portray polymer-supported metal or metal oxide nanoparticles as a novel type of hybrid polymeric/inorganic materials, which are capable of presenting features and application opportunities that have not been observed by solitary polymeric host materials or inorganic nanoparticles. We have labeled these particular classes of hybrid materials as polymer supported nanoparticles (PSNPs) in our context for the readers convenience. The distribution of metal and metal oxide nanoparticles throughout the PSNPs within the polymer phase has been performed in conformity with in-situ and ex-situ procedures. Despite the constant presence of metal and metal oxides as nanoparticles in PSNPs, yet there is a vast range of possibilities in regards to the morphology or physical arrangement of polymeric materials, which could differ from spherical beads to granules, membranes, fibers, and other structures. It can be stated from the observations that although polymer and metal/metal oxide nanoparticles can preserve their intrinsic qualities at the level of nano-scale, yet it is effortlessly possible to make modifications to supplement the overall features of PSNPs in different ways.

Metal Nanoparticles

Gold (Au)

The interest of many scientists has been captured by gold nanoparticles (Au-NPs), which is probably due to their fascinating qualities including simple synthesizing process and functionalization, chemical stability, low inherent toxicity (biocompatibility), and tunable optical and electronic properties (absorption, fluorescence, and conductivity) (Eustis and El-Sayed, 2006). There are three ways that the polymer scaffold in AuNPs–polymer composites can be utilized: (1) congregating the NPs and turning them into composite materials, (2) being modified as a matrix that can cause ordering and anisotropic orientation in clusters and on surfaces, and (3) taking the role of a functional element (e.g., possess an electronic property). In order to manufacture novel materials, the Polymer-mediated self-assembly of AuNPs can facilitate a flexible and practical method for this purpose. This “bottom up” technique can result in coupled AuNPs that contain varied nano-sized building blocks, such as linear, branched, and block copolymers, along with biopolymers that include proteins and DNA. The flexibility and reversibility of self-assembly procedures, which are conveyed through the means of certain molecular interactions, can provide the genesis of defect-free superstructures, while having the potential of being further studied throughout different fields varying from electronics and materials science to molecular biology (Ofir *et al.*, 2008). The modification of AuNPs is also possible by the utilization of carbohydrates or carbohydrate derivatives. Combemale *et al.* have demonstrated the production of AuNP neoglycoconjugates, which were decorated with mannose-6-phosphate (Man6P) analogues and procured through various synthetic methods (Combemale *et al.*, 2014). In order to evaluate their angiogenic activity, we have tested the AuNPs that had been functionalized with Man6P analogues through the usage of chorioallantoic membrane (CAM) assay, while the obtained results have indicated the

existence of anti-angiogenic activities in all the samples via the Man6P receptor, along with the lack of any apparent toxicity. Hyaluronic acid (HA) has been employed for the purpose of decorating AuNPs. A novel polysaccharide-Au nano-cluster supra-molecular conjugates has been fabricated by the usage of AuNPs, which bear adamantane moieties and β -cyclodextrin-grafted HA (Li *et al.*, 2014). Various anticancer drugs have been injected into the porous structure of the nanoparticle conjugates.

Silver (Ag)

The different and upgraded physicochemical qualities of silver nanoparticles (AgNPs), in comparison to the bulk silver, have been announced by various reports. The utilization of Silver nanoparticles in a vast range of applications have been evident, such as drug delivery and molecular imaging of cells, while various reports have emphasized their anti-inflammatory, anti-microbial, and wound healing activities (Braydich-Stolle *et al.*, 2005; Alt *et al.*, 2004; Kandamchira *et al.*, 2013). Different biopolymers, such as chitosan, alginate, etc., have been widely employed throughout the synthesizing procedures of nanoparticles. It has been observed in a particular research that the curcumin caged AgNPs were capable of causing an upgrade in the viscosity and self-assembly procedure of collagen, while advancing its mechanical and thermal qualities as well. Curcumin caged silver stabilized collagen stands as an exemplary candidate for biomedical implementations (Srivatsan *et al.*, 2015). In addition, the capability of AgNPs in being notable antimicrobial agents have been confirmed by several studies that had been carried out throughout the recent years, since these specified nanoparticles can counter different infectious diseases and take the role of a novel nano-medicine (Vellasamy *et al.*, 2014; Yazdi *et al.*, 2018c). The aim of the studies that have been carried out on bioconjugation of AgNPs were mostly pointed towards antimicrobials. The production of AgNPs decorated with proline-rich peptide C-Bac3.4 has been achieved in the course of a successful approach and thus, the bioactivity of these bioconjugates has been assessed in contrast to the functionality of their constituents such as bare nanoparticles and peptide (Golubeva *et al.*, 2012). In conformity with the obtained outcomes, the peptide-conjugated nanoparticles have exhibited pronounced antimicrobial activity in opposition to both 9 standard and multidrug-resistant bacteria.

Other metals

A great deal of investigations has been performed on synthesizing metal nanoparticles through the utilization of polymer networks as controlled environments (Caseri, 2000), which can provide an accurate control on the size and shape of nanoparticles, as well as three-dimensional organizations (Zhang *et al.*, 2004). Alginate has proved to be a successful polymer in controlling the progress of monometallic and bimetallic metal nanoparticles (Brayner *et al.*, 2007). Metal cations contain the ability to function as cross-linkers in order to produce a gel network and apparently get caught up within the specific cavities where they get positioned in a close proximity. Once a reduction is induced, these particular cavities can be perceived in the role of confined media that can restrict the development of metal nanoparticles. Based upon the alginate composition, we have observed the varying particle sizes, structures, and magnetic qualities of Ni and Co nanoparticles (Brayner *et al.*, 2007). It is possible to decorate PtNPs with the usage of nucleic acids, since this method has been employed as a label for the amplified biorecognition of DNA hybridization and aptamer-protein recognition events (Gill *et al.*, 2006). In the company of H_2O_2 and luminol, nucleic acid functionalized PtNPs can operate as catalysts in order to create chemiluminescence. Among the many types of catalysts, supported molybdenum catalysts are active and widely used for oxidative desulfurization (ODS) (Zhang *et al.*, 2004; Brayner *et al.*, 2007). SiC can be considered as a fine material for catalytic applications due to its defects and intrinsic structure. The main advantages of utilizing these bio-SiCs as catalyst supports include containing a low synthesis temperature and excellent catalytic properties, as well as being inexpensive and environmentally friendly raw material precursors.

Throughout the last few decades, an exceeding development in polymer nano-composites has happened due to their exceptional accreditations in structural, electrical, and mechanical utilizations. The incorporation of nano-fillers with polymer host can be quiet practical in the fields of biosensors, energy storage devices, photo catalysts, drug delivery, and etc (Gill *et al.*, 2006). The attributions of nano-structured materials in regards to miniaturized and smart futuristic technology have been acknowledged as a class of materials in the range of nanoscale, which can be disperses into polymer matrixes for intensifying the efficiency of high aspect ratio and load the potential of transferring. Through the employment of ultrasonication method, we have supplemented the production of polymer nano-composite in order to carry out the dispersing procedure of nanofillers; nevertheless, the controlled numbers of weight and size of the nanomaterials have been taken into account throughout the whole process. The main obstacle of this approach appears itself when the agglomerated formation has to be eradicated as the nano-filler confronts the host polymer. For the purpose of achieving a uniformed dispersion, we have adopted several techniques to functionalize the surface of nano-filler. Nowadays, various kinds of structures, including nanotubes, nanofibers, nanoribbons, and nanoparticles, have been discovered that can fulfill the demands for specific and required properties (Faupeil *et al.*, 2010). The utilization of conventional fillers, such as carbon black, silicates, and calcium carbonates along with lots of other reinforcing agents, have been perceptible in industrial applications, while their academic scale has faced a decrease (Muccini, 2006). A wide range of investigations has been performed on various polymers including conducting polymers (Polyaniline, polypyrrole, polythiophene, and polyfuran), since due to their high optical and conductive features, their applications in different fields of sensors, fuel and solar cells, EMI shielding, and supercapacitors have given fascinating results (Sharma *et al.*, 2018). The focus of scientific society has been pointed towards the augmentation of biopolymers-based nanocomposites due to the existing population, global changes in climate, and industrial pursuits. For the purpose of inventing new applications based on environmental implications, a lot of interest has been invested in the usage of various thermoplastic biopolymers and their nano-composites. The companion of nano-fillers can effortlessly improve the mechanical strength, electrical conductivity, anti-corrosion, thermal qualities, and etc of biopolymers and when the

high fabrication costs and inadequate characteristics of biopolymers are considered, their integration becomes a necessity (Lau and Hui, 2002; Tran *et al.*, 2010). Most of the biopolymers are known to be biodegradable and since they are derived from renewable resources, they have been labeled as harmless materials for the environment. The origins of natural and synthetic biopolymers are known to be living organisms, polynucleotides, polysaccharides, and biomass production, while the integration of a small portion of nano-fillers, e.g., polyethylene, polystyrene, etc. can be a replacement for many other utilized thermoplastics (Zhao *et al.*, 2005). In accordance with a review from literature, the interest of many scientists has been turned towards the various types of metal and carbon based nano-fillers, since these particular elements are capable of improving the qualities of biopolymer matrixes. Most of the reports have principally categorized carbon based nano-composites, while significant investigations has been performed on graphene and carbon nanotubes and the optimization of dispersion has been kept as a major concern. The motivation behind the attempts for enhancing the fabrication of metal-based polymer nano-composites is to surpass the disadvantages of polymer matrixes and thus, upgrade the biomedical implementations, environmental decontamination, edible packaging applications, and many other intentions that has been previously noted. Some of the methods that have been carried out for the synthesis of metal nanoparticles would be chemical vapor deposition (CVD), spray pyrolysis, electrodeposition and chemical procedures, sol gel process, rapid solidification, etc (Kumar *et al.*, 2002; Neville, 1993). To state some of the characteristics of metal nanoparticles, one can name their features of antibacterial agents, electrical conductivity, optical polarizability, and fine chemical qualities. In the course of their procedure, metal based nanocomposites encounter a decrease in their size and functionalization of surface which can apparently be utilized in plasmonic and sensing implementations (Faupel *et al.*, 2010). An opportunity for evolving bio-organic electronics has been created in the last decades by synthesizing polymer matrixes through the integration of nano-structured metal reinforcements (Muccini, 2006). Polymer nanocomposites have appeared in the position of new ingenious complexes that are constructed by layered nanomaterials including silicates or nano-clay. Nevertheless it must be mentioned that these particular elements contain deficient electrical and thermal conductivities and for the purpose of surpassing these drawbacks, the usage of carbon based nano-fillers, e.g., carbon black, carbon nanotubes, graphene oxide and its derivatives, is quite necessary. Carbon nanomaterials have displayed notable properties, such as containing high surface area, noncorrosive feature, light weight, and exceptional mechanical strength, which have labeled this substance as an appealing absorbent; however, the application of these specific materials has been restricted due to their expensive production costs (Sharma *et al.*, 2018). Throughout the different members of nano-fillers category, carbon nanotubes (CNTs) seem to contain the propensity for causing agglomerations within polymer matrixes to destroy their surfaces, which is treated with functionalizing agents in order to obtain homogeneous dispersion. The CNTs have been discovered by Iijima, which are graphite sheets that have been rolled into tube-like forms for the purpose of facilitating high strength composites, energy storage devices, biosensors, etc (Lau and Hui, 2002).

Metal Oxide Nanoparticles

Magnetite (Fe_3O_4)

Magnetite (Fe_3O_4) has been observed to be a common ferrite that contains a cubic inverse spinel construction. This particular compound has demonstrated rare electric and magnetic qualities, which are based upon the movements of electrons between Fe^{2+} and Fe^{3+} within the octahedral sites. The attraction that has been captured by magnetite is mainly focused on applications such as the removal of heavy metal (Tran *et al.*, 2010), electrocatalytic (Zhao *et al.*, 2005), and drug carriers (Liu *et al.*, 2009). Commonly, the synthesis of magnetite nanoparticles is carried out by utilizing the coprecipitation of ferrous (Fe^{2+}) and ferric (Fe^{3+}) ions which involves a base as well. Green and generic techniques are environmentally utilized through the composition of Fe_3O_4 nanoparticles while their potential applications are facilitated as well. As a biopolymer, sodium alginate can function as a reducing and stabilizing agent throughout the fabricating procedure of Fe_3O_4 nanoparticles (Gao *et al.*, 2008). The results of preliminary magnetic measurements have proved the existence of apparent ferromagnetic qualities that have the potential of being practical for high-density recording media in the upcoming nano-devices.

Zinc oxide (ZnO)

Throughout the metal oxide nanoparticles, ZnO nanoparticles (ZnO-NPs) have been selected to be utilized as a potential material for biosensing purposes, due to their exceptional features such as high surface area, high catalytic efficiency, non-toxicity, chemical stability, and strong adsorption capability (high isoelectric point ~ 9.5). The competence of Nano-porous ZnO in exceedingly improving the active surface area has been proved, which can be employed for strong adsorption of biomolecules (Singh *et al.*, 2007). The uniformly dispersed ZnO-NPs in chitosan (CHIT) have been employed through an examination for the purpose of modifying a hybrid nanocomposite film into indium-tin-oxide (ITO) glass plate. Moreover, Cholesterol oxidase (ChOx) has been inactivated onto the designated nano ZnO-CHIT composite film. ChOx/NanoZnO-CHIT/ITO bioelectrode has been applied to approximate the cholesterol that exists within the solution and the blood serum samples, which will also help in perceiving the other metabolites such as urea, glucose, uric acid that includes toxicants, etc (Khan *et al.*, 2008).

Cerium oxide (CeO_2)

A great amount of interest has been invested in CeO_2 nanoparticles (CNPs) throughout nanotechnology that has been caused by their beneficial applications including catalysts, fuel cells, and antioxidants in biological systems (Gagnon and Fromm, 2015; Tian *et al.*, 2015b; Arya *et al.*, 2016). Predominantly, cerium is capable of existing in two specific oxidation states, which are

Ce^{3+} and Ce^{4+} , and for this very reason, cerium dioxide can accommodate two varying oxide forms (Beaudoux *et al.*, 2016). The production of CNPs have been carried out by the employment of various routes and synthesis techniques including solution precipitation (Chen and Chang, 2005), sonochemical (Jimmy *et al.*, 2003), and sol-gel procedures (Darroudi *et al.*, 2014a). Nevertheless, the utilization of toxic solvents and reagents, high temperature and pressure, and the necessity of external additives as stabilizing or capping agents in the course of the reaction, can be counted as some of the disadvantages of exploiting the noted methods. Similar to the existing relationship between the physiochemical qualities of NPs and their synthesis method, the significance of NPs synthesizing procedure in biological applications is quite evident as well and for this very reason, the green synthesis of CNPs has attracted the attention of many researchers in recent years. In the role of macromolecules, natural polymers can also function as templates through the bio-directed synthesizing procedure of CNPs. Different reports have labeled egg white protein and honey as nutrients and natural materials for the green synthesis of CNPs (Kargar *et al.*, 2015b; Darroudi *et al.*, 2014b). On the topic of CNPs development, Kargar *et al.* (2015b) have suggested that the two substantial proteins of egg white, which are ovalbumin and lysozyme, are capable of operating as green binder/stabilizing agents. They have also announced the successful green synthesis of small CNPs, which had been stabilized by the means of agarose polymers via a sol-gel procedure (Kargar *et al.*, 2015a). When agarose powder is heated up to $>90^{\circ}\text{C}$, it commonly dissolves in water and as the temperature is lowered to $35\text{--}40^{\circ}\text{C}$, the formation of a semisolid gel can be observed that seems to be stable in a vast range of pH (from 3 to 9). In a comparable situation, Darroudi *et al.* have had synthesized CNPs through the utilization of starch, which has functioned in the role of a capping biopolymer (Darroudi *et al.*, 2014a). This starch-based mechanism has suggested that subsequent to dissolving starch in water, metal cations seem to get drawn towards the oxygens of existing OH branches. Darroudi *et al.* have also utilized Gum Tragacanth for the purpose of developing CNPs, which involved both chemical and biological procedures (Darroudi *et al.*, 2014c).

Other metal oxide nanoparticles

Chitosan and CNPs, which were based upon nano-biocomposite film and had been deposited onto the substrate of indium-tin-oxide coated glass, have been employed to co-immobilize rabbit immunoglobulin (r-IgGs) and bovine serum albumin for the purpose of detecting food borne mycotoxin (Kaushik *et al.*, 2009). The application of copper oxide NPs (CuO-NPs) can be regularly observed, which is probably due to their antimicrobial and biocidal features (Ren *et al.*, 2009). Due to their antimicrobial qualities, these particular CuO-NPs are often utilized in paints or fabrics in a polymer-coated form (Perreault *et al.*, 2012). In accordance with the available studies, chitosan has displayed exceptional antibacterial abilities for food packaging applications, which is probably due to being a biomaterial based nano-composite film that contains silver oxides (Tripathi *et al.*, 2011).

Silicon carbide materials have captured the interest of many due to their exceptional qualities, which includes semiconducting properties, excellent mechanical strength and thermal conductivity, chemical inertness, and outstanding thermal shock resistance (Zagorodni, 2006; Eustis and El-Sayed, 2006). Nano-structured SiC have proved to contain superior electrical, optical, and mechanical features, when compared to their bulk form, and seem to stand as an appealing candidate for various applications such as catalyst support, drug delivery, and hydrogen storage (Ofir *et al.*, 2008; Combemale *et al.*, 2014). The available synthesizing procedures for these materials involve various disadvantages such as the requirement of high-temperature synthesizing method and expensive raw precursors, as well as not being environmentally friendly (Li *et al.*, 2014; Braydich-Stolle *et al.*, 2005). Typically, surfactants or polymers are utilized as the templates for the production of porous materials, since the template method can be practical for regulating the structural properties, including surface area, internal porosity, and external shape (Alt *et al.*, 2004). However, it must be noted that many surfactants can cause toxic effects in animals, humans, and ecosystems while intensifying the propagation of environmental pollution as well (Kandamchira *et al.*, 2013; Vellasamy *et al.*, 2014). Even though the utilized polymers as templates are not fitted for biological applications next to containing petrochemical structures and requiring a large budget, yet natural biopolymers have proved to be inexpensive, nontoxic, and environmentally friendly materials that can be appointed as carbon templates (Yazdi *et al.*, 2018c). In addition to the mentioned advantages, natural biopolymers contain an uncountable number of structures. In a previous report, tragacanth, guar, xanthan, and Arabic gums with cellulose-like backbone had been utilized in the synthesizing procedure of nanostructured silicon carbide. Throughout this specific method, most of the sulfur compounds have been detached under a mild condition (Golubeva *et al.*, 2012; Caseri, 2000).

Perspective and Future Study

In recent years, the attention of many researchers has been focused on the natural biopolymer-based materials that are mainly due to their possession of desired features, which include biodegradability, biocompatibility, nontoxicity, and antimicrobial properties. The utilization of biopolymers by mankind is majorly involved in food applications or the production of clothing and furniture. Fossil fuel, oil for example, have been the dominant source for developing and fabricating almost every commercial product since the industrial time, such as plastic that is being utilized in an enormous scale at the present time. The requirements for these novel materials throughout the future of biopolymers will be massive and irresistible for manufacturers. Nevertheless, it is necessary to enhance the cost-effectiveness of these materials while specifically contributing to their sustainable advancement. The exceptional features of these polymers must be employed in their applications and it is quite vital that the constructed products would be developed based upon those properties. The recent appearance of bio-based products have been noticed and preferred over the petroleum or natural gas based products due to the uprising concern for tending and looking after the world we live in. There are several motivations behind the performed researches and developments of Biopolymers. By producing more

durable versions of biopolymers, their utilization can be remarkably intensified while the fabrication costs of these bio-plastics proceed to fall. Bio-plastics stand as an outstanding replacement for conventional plastics throughout their fields of applications, as well as other various sectors such as food packaging, plastic plates, cups, cutlery, plastic storage bags, storage containers or other plastic or composite material items that are available for sale; therefore, this evolution can be considered as a big step in having a more sustainable environment. The substitution of conventional polymers with biopolymers has never been this close to reality throughout its history. Nowadays, due to the induced progress in biotechnologies and the increased public awareness, bio-based polymers can be regularly perceived in many different fields that vary from commodity to hi-tech applications.

Throughout the performed examinations for discovering novel nanomaterials while concerning the goal of sustainable production and consumption, biopolymers have proved to contain several (potential) advantages including the employment of renewable resources to manufacture bio-based materials as the fundamental factor for expanding resource efficiency, the possibility of cultivating resources on a (at least) yearly basis, making the principle of cascade use possible since biomass is capable of generating energy after being utilized for fabricating materials, diminishing the footprints of carbon and GHG emissions that exist in different materials and products – resulting in saving fossil resources and thus, progress by gradually replacing them.

Characterization of Wood, Cork and Their Composites for Building Insulation

Pragya Gupta and Pradip K Maji, Department of Polymer and Process Engineering, Indian Institute of Technology Roorkee, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

Nowadays, there is a rapid growth in the building sector worldwide. Due to rapid urbanization, a significant part of total energy consumption and greenhouse gas emission is attributed to the building sector. Worldwide, one-third of the total energy is consumed for heating or cooling the buildings. The predicted demand for energy consumption is increasing 8% annually due to sharp income and population growth around the country. Recently, the European Union and developing country administration have introduced building energy efficiency program and regulation for commercial and residential buildings to mitigate the requirement of energy consumption. These kinds of program will be helpful for the planet by reducing greenhouse gas emissions. The energy consumption for heating or cooling the building is strongly dependent on the properties of building envelope. The appropriate selection of design and components of building envelope as per surroundings climate are the key factors for reducing the space heating and cooling (Al-Homoud, 2005). In a broader context, insulation is an efficient tool to reduce energy consumption in the building sector. Therefore, the optimum thickness of insulation and type of insulation materials for building envelope are the key points for the subject of investigation. The insulation thickness is mainly dependent on construction materials, shape of the building, insulation material, energy category and its cost and the efficiency of heating and air-conditioning system. Hence, the optimum thickness of insulation is the function of the cost of insulation materials and energy saving during the service time of insulation material, illustrated in Fig. 1. These kinds of investigations help us to estimate the demand for energy usage, size of heating and air-conditioning system as well as desirable thermal comfort of residents.

The adequate choice of building insulation is not only to fulfill the criterion of thermal performance but also to consider some other non-thermal features such as fire resistant, water vapor permeability, acoustic insulation, and impact on occupant's health etc. This is a holistic approach to choose the insulation material for the improvement of the building envelope.

Historical Development of Wood and Cork-Based Building Insulator

The study of historical development viewpoint is necessary to understand the requirement of different characterization for building insulation. In ancient civilization, wooden houses had been used for the residing purpose. But the peoples were not aware that the insulation was carried out by wood-based structure. In the early ninetieth century, concrete and cement materials had been adopted due to structural stability and mechanical properties enhancement. At the same time, energy consumption and environmental pollution were raised by the building sector. Just then, the researchers and scientist have shown their interest to save the earth. There are few reports based on thermal insulation in early 1970. The biobased building insulation was a new area intended towards research. In the mid-nineties, some researchers had worked on building insulation. Previously, the objective of the building was just for living and staying purpose, nobody was concern about environmental performance and energy conservation. Afterward, a storm had come in this precise space of investigation due to numerous regulations in the field of energy conservation and pollution. Consequently, attention was paid towards renewable insulation materials as well as conventional insulation materials. The research interest in the direction of biomaterial-based building insulation increases from the year 2010 due to economic crises. Environmental protection and energy conservation laws were taken worldwide. On the other hand, there

Fig. 2 Thermally comfort building.

was a rapid growth in the demand for indoor air quality, which leads towards the air-conditioning system and furthermore energy consumption (Liu *et al.*, 2017). Hence, the demand for energy conservation was moved towards the search for an eco-friendly way to fix a barrier against heat flow. Thus, Bio-based insulation material was drawn into attention to keep the heat flow from space to surroundings or vice-versa. In the current time, widely the people want to keep calm in the workplace as well as in the home, hence noise reduction or soundproof insulation system are also utilized as an acoustic insulation system. The objective of building insulation is building energy savings and environmental protection which moves towards the study of characterization of bio-insulation materials for building application.

Importance of Insulation In Building Sector

Building insulation is considered as a simple and highly efficient technique for energy saving, which can be applied in the residential, industrial and commercial division. Thermal insulation technique reduces energy utilization and thus protects our environment as well as enhances the lifecycle of the building by protecting from the weather. A building with seamless insulation is depicted in Fig. 2. It is quite clear in the image that, during winter season insulation keep the space warm and heat is not dissipated from space to surroundings. Whereas, in the summer season the outside heat cannot pass through the insulation and air-conditioning make a thermal comfort without wasting the energy. The key features of building insulation are listed here.

Thermal Comfort

Thermally comfortable feelings are strongly dependent on space air temperature and surroundings surface temperature. In a non-insulated space, a draft is created between space and surroundings due to huge temperature differences. Hence, an enormous amount of energy is required to create a thermally comfortable zone. Whereas, a small temperature difference in the air is maintained between the system and surroundings by applying insulation with wall, roof, and floor in the building. This helps to reduce the reliance on energy consumption and also extends the periods of thermal comfortable conditions.

Environment Protection

Building insulation leads to cost saving by reducing fuel consumption, which is also associated with less CO₂ emission. Less energy consumption leads to less environmental pollution. According to a report, insulated building panel reduced 45% environmental pollution as compare to non-insulated building panel.

Acoustic Insulation

Apart from thermal insulation, the insulation materials should be able to absorb intruding sound waves and contrast sound transmission. Acoustic insulation is the capability of insulation material to dissipate the sound energy due to resonance or thermal and friction loss (Schiaivoni *et al.*, 2016). Generally, sound absorption materials are good thermal insulator but vice-versa is not true. Because sound absorption requires open cell porous structure and the open porous cell captures the heated air molecules is also a good condition for thermal insulation. Closed cell porous structure is good for thermal insulation but it does not work for acoustic insulation because it requires movement of air inside the insulation material.

Fire Retardant

Building insulation materials should be a flame retarder. If the building insulation is made up of chemically treated flame retardant materials, it will play a crucial role during flame devastation and prevent the flame propagation from outside to inside space.

Vapor Condensation Prevention

The proper design of insulation material assisted to reduce water vapor condensation in case of low temperature.

Working Principle of Building Thermal Insulator

The aim of insulation is to keep a hygienic climate and comfortable temperature of the space by preventing the heat flow between the building and surroundings. All the insulation materials work on the basic principle that heat always flows from warmer to a colder place. Hence in the winter season, building insulation prevents heat flow from inside to outside areas and vice versa for the summer season. The strategy of thermal insulation is to achieve low thermal conductivity. The low thermally conductive material demonstrates the ability to use a thin building envelope. The insulation material must reflect high thermal resistance (R -value) and low thermal transmittance (U -value). The thermal conductivity of a system depends on several factors (Eq. (1)), which is as follows:

$$\lambda_{\text{total}} = \lambda_{\text{conduction}} + \lambda_{\text{convection}} + \lambda_{\text{radiation}} \quad (1)$$

In order to achieve low total thermal conductivity (λ_{total}) of insulation material, each of the contributions should be as low as possible. Thermal conduction of a material is based on two factors i.e., solid conduction and gaseous conduction. In the case of insulation, solid conduction is devoted to phonon phenomenon. Thermal energy transports through solid by lattice vibration with the help of chemical bonds between atoms. Whereas gaseous conduction takes place through the collision of gas molecules with each other and thermal energy transfer through one molecule to another (Jelle, 2011). Thermal convection drives via thermal mass transport of air or moisture between the pores. One of the best ways to decrease thermal convection is to reduce the pore size of insulation material. Hence, the air molecules are entrapped within the pores and interacted within the pores walls. The phenomenon is termed as Knudsen effect. Thermal radiation is based on the emittance of electromagnetic radiation within the infrared region.

All these thermal contributions basically depend upon the temperature difference. Building insulation materials have to fulfill a series of requirements. Some other requirements such as low density, high porosity, resistant to fire as well as low thermal conductivity restrict the selection of material and solutions for building insulation.

Manufacturing Process of Building Insulator

There are several preparation methods described by numerous authors according to raw material and end-user application (Liu *et al.*, 2017). Some of the common methods are as follows.

Bonding

The binding agents such as glue, starch, aluminum sulfate and some other resins are used to combine loose raw material like jute, flax, hemp and cellulose in the form of board or slab.

Pressing

A press based on high pressure at ambient condition is utilized to combine loose fill fibers and particles by compressing the material in the form of the homogeneous body. This particular method reduces voids without adding supplementary material.

Hot Pressing

In this method, high temperature and high pressure are applied to bound the particles and form a solid board.

Injection Molding

The composites slab is prepared by molding process. In this method, the polymer melt and reinforcing materials are mixed at certain pressure and temperature. Then the solution is injected in the definite shape and size of the mold.

Fig. 3 Recent publication based on different characterizations for building insulation application. Reproduced from Liu, L., Li, H., Lazzaretto, A., *et al.*, 2017. The development history and prospects of biomass-based insulation materials for buildings. *Renewable and Sustainable Energy Reviews* 69, 912–932.

Foaming

The homogeneous porous structure in solid material is generated by the physical or chemical foaming process. Initially, the polyurethane and polystyrene based composites foams are prepared by chemical and physical foaming process. In the recent scenario, most researchers and scientists have worked on wood and cellulose-based thermal insulation system. The authors basically focused on nano-technological synthesis routes like freeze drying or supercritical drying for the preparation of bio-based thermal insulator. These kinds of drying processes are costly and can not be adopted for commercial purpose. According to a survey, the foaming molding process has a strong potential towards bio-insulations despite very few research group have been carried the work out up to now. The foaming molding process can reduce density significantly, while porosity can be highly enhanced. Moreover, the mechanical properties such as compressibility, bending strength, etc. can be improved as well by properly tuning the processing conditions.

Natural Form

Wood and cork based biomass can be used the same as the raw form.

Others

Some other processes such as punching and hydroentanglement etc., can be used for the preparation of building insulation materials according to end use application.

Basic Criterion for Selection of Building Insulator

There are several characterizations to validate the ability of building insulator like thermal characterization, acoustic characterization, life cycle assessment, resistant to fire and moisture resistant etc. Thermal properties such as thermal conductivity, thermal resistivity, thermal diffusivity, heat capacity and coefficient of thermal expansion are mostly explored (Fig. 3) for building insulation application. Table 1 shows various characterization, method and criteria.

The properties are described as follows:

Thermal Insulation

Thermal insulation is the ability of the material or a system to resist against heat flow for the system to surroundings or vice-versa. Thermal insulation hinders the heat flow through conduction, convection, and radiation. The researchers mainly focused on thermal conductivity of building insulation material.

Table 1 List of characterizations, method and specimen criterion

Characterization	Method	Criteria
Conditioning	ASTM C 870	Conditioning prior to testing
Thermal conductivity ($\text{W m}^{-1} \text{K}^{-1}$)	EN 12664	Low thermal resistance
	EN 12667	High thermal resistance
	EN 12939	Thick material
	ASTM C 518	Heat flow meter apparatus
	ASTM C 177	Guarded hot plate apparatus
Thermal diffusivity ($\text{m}^2 \text{s}^{-1}$)	ISO 8990	Hot box method
	ASTM E 1269	Differential Scanning Calorimetry
	ISO 22007-3	Temperature wave analysis method
	ISO 22007-2	Transient plane heat source(hot disc)method
	ISO 22007-4	Laser flash method
Density (kg m^{-3})	EN 1602	Apparent density
	ASTM C 303	Board and block type insulation material
Specific heat capacity ($\text{J kg}^{-1} \text{K}^{-1}$)	ISO11357	Differential Scanning Calorimetry
Acoustic insulation (dB)	ISO 717-1	Weighted sound reduction index, R_w
	ISO 16283-1	Apparent sound reduction index, R_0
	ISO 10140	Normalized impact sound pressure level, L_n
	ISO 717-2	Normalized impact sound pressure level, L_n
	ISO 354	Sound absorption coefficient
	ASTM C 42309a	Noise reduction coefficient, NRC
	ASTM D 3801	Burning characteristics of solid plastics in a vertical position
	ASTM D 5048	Comparative burning characteristics and resistance to burn
Flame retardancy	UL 94	Flammability of Plastic Materials
	ISO 5660	Reaction to fire test
	ASTM E 1354	Heat and smoke release rate using calorimeter
	ASTM C 356	Linear shrinkage
Coefficient of thermal expansion ($^{\circ}\text{K}$)	ASTM C 356	Linear shrinkage
Vapor retention capacity	ASTM E 96	Water vapor transmission rate

Thermal conductivity

Thermal conductivity is “the time rate of steady state heat flow through a body of per unit area (1 m^2) by inducing per unit (1K) thermal gradient in the perpendicular direction of isotropic substance”. The thermal conductivity of wood and cork is affected by various factors such as density, porosity, extractive content, moisture content, grain direction, structural irregularities, and temperature. Generally, Thermal conductivity is directly proportional to density, moisture content, and temperature.

Thermal diffusivity

Thermal diffusivity is an important criterion to measure how rapid a system absorbs energy from surroundings. It is the ratio of thermal conductivity of a substance to its heat capacity and density.

Thermal resistivity

Thermal resistivity is associated with R -value of insulation. Thermal resistivity is the capability of a substance to resist the conduction, convection, and radiation by opposing the heat flow. It is the ratio of the thickness of insulation materials to its thermal conductivity.

Thermal transmittance

Thermal transmittance is associated with U -value of multi-layered insulation material. Thermal transmittance is the heat flow through per unit area of anisotropic and non-homogeneous insulation material due to increment of 1°K temperature.

Coefficient of thermal expansion

The coefficient of thermal expansion is the change in the dimension of substance due to change in temperature.

Density

Density is the most important factor which influences the thermal conductivity of insulation material. The density of any specimen affects the heat flow due to solid conduction.

Porosity

The porosity of any specimen is affected by the particle size of raw material and size of voids. Porosity is the void fraction of specimen with respect to their total volume. It is calculated by Eq. (2)

$$\epsilon = 1 - \frac{\rho}{\rho_s} \quad (2)$$

where, ϵ = porosity of insulator (%), ρ = density of final product (i.e., weight with respect to their volume), and ρ_s = skeleton density of the product.

Life Cycle Assessment

The environmental impact of building insulation is an important criterion for the selection of material. Global warming and energy consumption are the basis for the life cycle assessment of insulation material. The direct or indirect burden on the environment due to energy consumption influences towards eco-design and energy efficiency building insulation. Cork, wood and other valuable natural material for building applications have shown great ecological value. It is also very interesting from a sustainability perspective because, in addition to its low emissions and the great potential for capturing CO₂, it generates economic revenues, provides jobs and development in rural areas, and allows many environmental services such as forest preservation, biodiversity conservation, and wildfire prevention.

Mechanical Properties

Mechanical properties are secondary characterizations in building insulator sector, that does not affect the performance of insulation, but it varies the credibility of insulation material in the presence of the external load. The common mechanical properties for building insulation application are as follows.

Modulus of elasticity

Modulus of elasticity is the ratio of stress to the strain of specimen in the elastic zone. It is also termed as elastic modulus or Young's modulus.

Modulus of rupture

Modulus of rupture is the ratio of maximum sustainable load and the fracture cross-section area of the specimen. It is calculated from maximum tensile strength or maximum shear strength up to the failure of a sample.

Flexural strength

Flexural strength is the ability to sustain bending without breakage of the specimen.

Internal bonding strength

The bonding strength is the ability to sustain load in the lateral dimension of the specimen.

Tensile strength

Tensile strength measures the ability to sustain longitudinal stress without breaking the specimen.

Compression strength

Compression strength is defined as the bearing capacity of the specimen under the action of pressure or compressive stress along the axis of the applied load.

Impact strength

Impact strength is the toughness of specimen or energy-absorbed per unit cross-section area. It is defined as breakage under impact or sudden load.

Durability

Durability is the ability of bio-based insulation material to resist the corrosion or environmental damage during long term application.

pH

pH is the hydrogen ion concentration present in a specimen. The pH value of insulation explains the microbial contamination of bio-insulation material, which refers to the long term durability of the specimen.

Antimicrobial activity

Wood and other biomaterials are prone towards several microbes like termite. In recent time, bio-insulation materials are present in the market with an antimicrobial coating to prevent mold and microbial proliferation that enhances long term durability of insulation material.

Microstructure

The morphology and structural characteristics show strong relation with the thermal and mechanical properties of insulation material. The microstructural characterization will contribute to justify and correlate structure and properties relationship. Several analyses like scanning electron microscope, X-ray microtomography, scanning probe microscopy, and optical microscopy has been reported for microstructural characterizations by several authors.

Volatile Organic Compound

If the insulation material is made by adding an artificial binding agent, then it may be a possibility that binding agent leached out some organic volatile compound in the environment during installation period or during the whole service life of the building.

Moisture Absorption Behavior

The biomaterials like wood, hemp, flax, bamboo, and cellulose etc., are susceptible to moisture. If the insulation materials are used in the interior or exterior side of walls instead of a sandwich panel, hence a hydrophobic coating is required to maintain the mechanical and thermal properties of insulation material.

Swelling thickness

Swelling thickness is determined by water absorption performance and expansion ratio of insulation material while immersing the specimen in water for 24 h.

Coefficient of moisture absorption

It is the amount of moisture absorbed per unit volume by exposing the specimen in the air at atmospheric condition.

Water vapor permeability

It is the ability to transmit the moisture through the specimen. The bio-insulation materials are made up of the porous structure and suitable to make desirable moisture in the space and comfort for the occupants.

Moisture content

Moisture content is also an important factor for wood-based insulation materials. Several authors have already discussed the variation in the thermal conductivity at a different moisture content of the specimen. The probable fact is that the thermal conductivity of water is higher than air and that is why thermal conductivity increases by varying the moisture content.

Several Types of Wood and Cork-Based Insulation System

Thermal insulation is playing an important role in the building sector. Several types of conventional materials such as glass wool, mineral wool, vermiculite, expanded perlite, phenolic foam, polyurethane are also considered as building insulation materials. The main drawbacks of conventional insulation materials are the depletion of nonrenewable sources and environmentally hazardous. Apart from that, several authors have reported building insulation materials based on renewable and natural sources. For the reference purpose for the current situation of research, hemp is considered as the most explored biomaterial for building insulation application. Around 17.4% of publications are on hemp, however; sunflower, cork, corn, wood, coconut, straw and flax cover 74% of total research interest. Some other biomaterials are not explored yet, for instance, durian, pineapple, sisal, reed, bamboo, olive and grass covers 8.3%. Some common bio insulation materials are as follows.

Cork

Cork is used for several applications by mankind from the last 5000 years. Cork is extracted from the outer bark of Oak "*Quercus suber L.*" tree. Cork is a natural, sustainable and renewable material because it does not damage the tree. The oak tree bark regenerates every 10–12 years depending upon the region until the 180–200 years age of the tree. Cork consists of ligno-cellulosic structure and 30%–50% suberin as an aliphatic polyester. The unique properties of the bio-derived material are its visco-elasticity and hydrophobicity. The cellular structural cork demonstrated as versatile acoustic, vibration, electric and thermal insulator, flexible, and a dielectric material. Cork depicted the extra-ordinary properties due to its closed cell wall structure ([Fig. 4](#)).

Fig. 4 Cellular structure of cork (a) transverse (b) longitudinal direction. Reproduced from Fernandes, E.M., Correlo, V.M., Chagas, J.A., Mano, J.F., Reis, R.L., 2010. Cork based composites using polyolefin's as matrix: Morphology and mechanical performance. *Composites Science and Technology* 70 (16), 2310–2318.

Basically, cork is a collective unit of approximately ten million cell walls per cubic centimeter, bounded by resin. The maximum percentage of cork is generated in southern Mediterranean countries especially Portugal. The cork forest rises environmental advantageous such as carbon-dioxide consumption, hydrological cycle, prevent desertification and maintains the habitat for several plant and animal species (Gil, 2015). There are four different types of building material produced from cork. The first one is obtained as steam treated thin and fine laminates from natural cork. The second one is produced by hot pressing of agglomerated cork at 350°C and 300 kPa. The final color is brown and is used for thermal and acoustic insulation (Hernández-Olivares *et al.*, 1999). As a substitute for building materials, cork-rubber and granules are used as a reinforcing agent in composites.

Wood

Basically, wood is collected from ecological forestry system. Wood is a natural thermal insulator consist of ligno-cellulosic masses. Wood is basically subdivided into two categories; softwood and hardwood. The main difference between the trees is based on the way to reproduce. Softwood trees are gymnosperm and reproduced by uncovered seed. Pine, cedar and other conifers are the examples of softwood trees. While, hardwood are angiosperms and reproduced from covered seed such as fruit, acorns, and nut. Mostly, hardwood drops their leaves in the fall season. The selection of wood is based on the characteristics, easiness, the ability to sustain load and climatic conditions etc. Several types of woods and its characteristics are briefly described here,

Softwood

- *Cedar*

Cedar is lightweight and low-density wood with excellent resistant towards decay. The aromatic oil wards of cedar show outstanding resilient against microbial growth and insects.

- *Cypress*

The specialty of cypress is its sustainability against extremely wet conditions. Hence, it can be used in the outer most structure of building, docks, and decks.

Fig. 5 Transparent wood based rooftop. Reproduced from Li, T., Zhu, M., Yang, Z., *et al.*, 2016. Wood composite as an energy efficient building material: Guided sunlight transmittance and effective thermal insulation. *Advanced Energy Materials* 6 (22), 1601122.

Hardwood

- *Balsa*

Balsa is mostly harvested from South America and Ecuador. It is a lightweight and durable wood with exceptional strength.

- *Birch*

The thin paper bark of the birch tree makes it superior for insulation purpose. Birch is massively found in Canada and northern America.

The cellulose is basically provided low thermal conductivity and lignin acts as a binder in wood. Due to excellent mechanical strength, wood-based panel and the pillar are already used in construction from the decades. Most of the cases, wood fiber based panel or board is used for building insulation. Hence the sawmill industries residue and another type of wood waste can be utilized in the preparation of insulation materials. Instead of lignin, different kind of binders such as aluminum sulfate is applied as a binder, which also acts as a pesticide and wood preservative. The thermal conductivity of wood-based material depends upon temperature, humidity, moisture, density, and microstructure. In a recent report by Li *et al.* (2018), transparent wood based structure was prepared as energy efficiency and light harvested building material. The transparent wood based system is shown in Fig. 5.

Hemp

Hemp is harvested from "*Cannabis sativa L.*" and mostly used as textile fiber. Hemp consists of a surface layer, 20–50 bundles of bast fiber, a wood-based core and a central lumen. The bundles of bast fibers utilize as a raw material for the preparation of thermal insulator. The hemp can be used as a loose fill insulator or as a board with the binder, which is advantageous on different raw materials.

Kenaf

Kenaf is a potential material for developing low-density boards which can be further used for thermal insulation products. The Kenaf plant comprises of long outer bast fibers with an inner core suitable for wide range applications. Kenaf is usually free from insects and rodents attack as it lacks protein. These fibers are usually supplied with fire retardants and polyester.

Flax

Flax (*Linum usitatissimum*) is already utilized by the Egyptian since 5000 BCE. The flax plant consists of 70% cellulose, having the ability to hold air. Hence, Flax is shown excellent thermal insulation properties over other materials.

Coir Fiber

A natural fiber isolated from the husk of coconut or collected as a waste product from the coconut industry constitutes the term coir. This fiber is one of the few natural fibers resistant to deterioration caused by saltwater. These fibers have inherent high mechanical strength. These fibers also act as a good sound absorber when compressed in bales.

Low density and high strength nanofibrillated cellulose aerogel for thermal insulation application. *Materials and Design* 158, 224–236.

Jute

India and Bangladesh are the leading producers of jute. Jute fibers are less expensive and highly elastic in nature showing excellent resilient property which is utilized in floating floors. These fibers can be utilized as sound, electrical or thermally insulating material.

Cellulose

Cellulose acts as an environmentally friendly material for application in building insulation having suitable acoustic properties and low embodied energy per kg of material. Cellulose fibers used for insulation mainly comprise of recycled paper fibers having certain drawbacks like hygroscopic nature of cellulose and fungal growth and combustibility and are hence are treated with additives like fire retardants and fungal growth inhibitor. Mainly cellulose fiber utilized for insulation is available in two forms one is a prefabricated panel in which fibers are bound using polyester resin and second where fibers are supplied for ceiling and walls application as loose fibers (Hurtado *et al.*, 2016).

Nanotechnological Revolution in Wood and Cork-Based Composites

Nanotechnology is a scientific tool, which enhances the performance of thermal insulation material. The basic criteria of nanotechnology is that the dimension of material should be between 0.1 and 100 nm (Jelle, 2011). Nowadays, the energy efficiency building regulations and nation-wise standards are more rigid. The primary objective is to diminish the heat flow through the walls. It can be done either by means of increasing the thickness of wall insulation or enhance the performance of insulation material. In the case of insulation, the void space of material should be in nano-range (Fig. 6). The nano insulation material is based on the fact that heated molecules collide with pore walls instead of other molecules follow the Knudsen effect. The elimination of molecular collision lowers the thermal conductivity and enhances the efficiency of nanotechnological insulating materials.

The nano-insulating materials are basically vacuum insulation panel, gas insulating panel, phase change material and aerogel. The low density and highly porous structure with pore size between 2 and 50 nm is termed as “aerogel”. The building insulation based on aerogel is the current subject of investigation. Several researchers have reported cellulose,

Fig. 8 X-ray tomographic analysis of nanofibrillated cellulose aerogel by varying concentration, (a) 3 Dimensional view of low density aerogel similarly for (b), (c) and (d); (a' and a'') local density distribution of aerogel similarly for other images. Reproduced from Gupta, P., Singh, B., Agrawal, A.K., Maji, P.K., 2018. Low density and high strength nanofibrillated cellulose aerogel for thermal insulation application. *Materials and Design* 158, 224–236.

pectin, starch etc., for super thermal insulation application. Different kinds of additives such as nanoparticles, clay, graphene, and specialty polymers can be added as a reinforcing agent to enhance mechanical properties as well to decrease flame susceptibility and brittleness of bio-based aerogel. Gupta *et al.* (2018), had worked on cellulose nanofibers based aerogel for thermal insulation application. The authors explained the difference in the thermal conductivity phenomenon between conventional foam and aerogel via pictorial view (Fig. 7). It is clear in the picture that more solid content enhances the density of structure, which boosts the solid conduction. While due to large particle size of primary materials generate large voids in the specimen that helps to enhance gaseous conduction as well as convection phenomenon. Whereas, in the case of aerogel, the diameter of fibers is in nano-range having a low radius of curvature that assisted to squeeze the fibers and compresses the pores of structure within 2–50 nm range. The phenomena advantageous to capture the heated air in the pores and the air molecules crashed within the internal cell wall without transmitting the heat conductivity.

X-ray micro-tomographic analysis is basically performed to evaluate the three dimensional and homogeneous structure of any porous material. The analysis facilitated to investigate local density distribution and cracks in the microstructure, which help to correlate the thermal conductivity and mechanical properties of specimen. Fig. 8 shows the x-ray micro-tomographic images at a different density of cellulose nanofibers based aerogel. The top view and bottom view of local images (Fig. 8) depicted that aerogel was homogeneous throughout, while the three dimensional images are self-explained; that is by varying the solid content, the void space is reduced and aerogel should be more homogenous which accelerate to reduce the thermal conductivity of aerogel. The authors reported that thermal conductivity of insulation depends on the amount of solid material, moisture content, density and pore size of aerogel. The optimum thermal conductivity was reported to be $0.0255 \text{ W m}^{-1} \text{ K}^{-1}$ at aerogel density of 11.9 kg m^{-3} . A comparative study between thermal conductivity vs. density in addition to constituent of aerogel (Fig. 9) was reported by Gupta *et al.* (2018).

The exploration of thermal conductivity of aerogel is predominantly dedicated to the energy efficient building insulation application. Nanowood based anisotropic, lightweight and super thermal insulation materials were also explored by Li *et al.* (2018). Wood-based nano-insulation material had revealed four main characteristics to explain the super thermal insulation performance. Primarily, the porosity of nanowood was increased to 91% while pristine wood has 60% porosity. The higher porous nanowood

Fig. 9 Comparative study between numerous reports on aerogel for thermal conductivity as a function of density. Reproduced from Gupta, P., Singh, B., Agrawal, A.K., Maji, P.K., 2018. Anisotropic, lightweight, strong, and super thermally insulating nanowood with naturally aligned nanocellulose. *Science Advances* 4 (3), eaar3724.

lowers the thermal conductivity. Secondly, the elimination of undesirable components of wood such as lignin and hemicellulose reduce the aggregates by weakening the interaction between cell wall fibrils that lowers the heat conductivity in lateral dimension (Fig. 10). The aggregated nanowood resulted in the anisotropic heat flow in the direction of fibers alignment. While the concluding remarks to lower the thermal conductivity of nanowood was described by several authors that pore size below mean free path of air predominately reduces the thermal conductivity of nano insulation materials.

Survey on Wood and Cork-Based Building Insulation

As a building insulation material, thermal conductivity is one of the most important criteria of subject of the investigation to evaluate the performance. The quantitative evaluation of thermal conductivity permits the assessment of the effectiveness of different insulation material (Al-Homoud, 2005).

Influence of Density on the Thermal Conduction

Thermal conductivity and diffusivity of birch (hardwood) had been investigated by Suleiman *et al.* (1999) via transient plane source method. The density and thermal conductivity are shown in Table 2. By varying the density, date palm fibers based board was prepared by Ali and Alabdulkarem (2017). The date palm fibers board was prepared by using corn starch binder. The authors

Table 2 Density and thermal conductivity of several biomaterials

Specimen	Density (kg m^{-3})	Temperature ($^{\circ}\text{C}$)	Thermal conductivity ($\text{W m}^{-1} \text{K}^{-1}$)
Birch (Hardwood)	680	21	0.323
	567	21	0.293
	543	21	0.291
	680	100	0.370
	567	100	0.309
	543	25	0.318
Mixed cork	162	25	0.045
Gypsum/ palm (10%)	753	25	0.15–0.17
Gypsum/cork (20%)	578–864	25	0.12–0.19
Concrete/cork (10%)	2100	25	0.96
Cement/hemp shives (40%)	1040	25	0.11
Plaster/Wheat fiber (25%)	1699	25	0.33
Plaster/Barley fiber (25%)	1617	25	0.29

Cement/coconut coir fibers (10%)	19,801	25	0.38
Cement/coconut coir fibers (15%)	1800	25	0.37
Cement/oil palm fibers (5%)	2030	25	0.40
Cement/oil palm fibers (10%)	1990	25	0.30
Cement/oil palm fibers (15%)	1970	25	0.27

**Fig. 11** *R*-value of date palmwood-based insulation material. Reproduced from Ali, M.E., Alabdulkarem, A., 2017. On thermal characteristics and microstructure of a new insulation material extracted from date palm trees surface fibers. Construction and Building Materials 138, 276–284.

had reported that thermal conductivity of boards is a function of temperature and density. The value of thermal conductivity increases by increasing the density and specimen temperature. The increment in the density enhances conduction as the solid transports the heat by phonon scattering due to lattice vibration of atoms and several authors have reported the same fact.

The date palm fibers based board has thermal conductivity between 0.0475 and $0.0697 \text{ W m}^{-1} \text{K}^{-1}$ with respect to density between 176 and 260 kg m^{-3} at 20 – 70°C (Ali and Alabdulkarem, 2017). Different varieties of date palm wood based materials for heat insulation is reported by Agoudjil *et al.* (2011). The mean thermal conductivity value is reported to be $0.083 \text{ W m}^{-1} \text{K}^{-1}$ at atmospheric condition.

Thermal resistance (*R*-value) of insulation measures, the effectiveness of insulation. The *R*-value of insulation depends on the thickness of insulation materials, thermal conductivity at a specified temperature and density. *R*-values of date palm fiber at different densities are shown in Fig. 11. The variation in the *R*-value of date palm fiber-based insulation with respect to temperature is reported as 18.49% for 176 kg m^{-3} , 18.32% for 184 kg m^{-3} , 18.61% for 260 kg m^{-3} and 16.91% for 207 kg m^{-3} (Ali and Alabdulkarem, 2017).

Fig. 12 Thermal conductivity of rice straw based board by varying density. Reproduced from Wei, K., Lv, C., Chen, M., *et al.*, 2015. Development and performance evaluation of a new thermal insulation material from rice straw using high frequency hot-pressing. *Energy and Buildings* 87, 116–122.

R -value of insulation had been investigated for waste cork based mortar and cement composites. The authors reported huge enhancement in R -value of insulation by incorporating waste cork. Different composition based on particle size and content of mortar, cement, and the waste cork had been prepared for characterization. The thermal conductivity of composites is reduced by 16% and 30% after addition of 10% and 20% waste cork as a reinforcing agent (Panesar and Shindman, 2012). The R -value of insulation increased from 0.059 to 0.086 m² K W⁻¹ and thermal conductivity decreased from 1.14 to 0.79 W m⁻¹ K⁻¹ by incorporating 20% waste cork. A 46% increment in the thermal resistivity was found after the addition of 20% waste cork in the composite. The oil palm fibers and coconut coir fiber reinforced cement composites also demonstrated a significant reduction in thermal conductivity coefficient with respect to control cement specimen (Lertwattanakul and Suntijitto, 2015). The incorporation of natural fibers had shown a positive effect on the thermal insulation performance of composites. The density and thermal conductivity are shown in Table 2. The thermal conductivity of pure natural particleboard based on different composition had been investigated by Khedari *et al.* (2004). The conductivity of composites with respect to density is demonstrated in Fig. 12. The authors described that density of fiberboard is directly proportional to the thermal conductivity because high dense packing of natural fibers shrinkages the voids and spaces and enhances the solid conduction which is the main factor of thermal conductivity. The authors also explained that, at the particular density, the thermal conductivity is varied due to different types of fibers used during sample preparation. The high amount of coconut fibers increases thermal conductivity as compared to durian fiber. This is due to the shape and size of the fiber which affects the porosity and structure of fiberboard.

Another insulation material based on rice-straw was prepared by Wei *et al.* (2015) by the hot pressing method. The authors also correlated the variation in the thermal conductivity with density and particle size. They had prepared a 40 mm thick sheet based on rice straw with a density in the range of 200–350 kg m⁻³. The thermal conductivity of rice straw based board is demonstrated between 0.051 and 0.053 W m⁻¹ K⁻¹. Rice straw is agricultural waste residue that is very lightweight and porous material with a significantly lower value of thermal conductivity. The authors reported a linear relationship of thermal conductivity with respect to density, which is shown in Fig. 12.

The thermal conductivity increases with density as the amount of solid content increases, heat conduction by solid also increases. So, the pore size of the solid board also decreases significantly with the increment in density, and thermal conductivity of rice straw is higher than the air which is also a responsible factor for the enhancement in thermal conductivity.

The density of any porous structure depends upon particle size and void space. For a specified density of board, if the particle size of raw materials decreases, it decreases the pore size of the board. The small pores capture the heated air due to the scattering effect of phonon and lower the thermal conductivity, whereas, in case of larger pores the heated air pass throughout the board following the law of thermal convection and increases the quantitative thermal conductivity (Niemz and Sonderegger, 2011). Due to the variation in the particle and pore sizes of the board, the thermal conductivity of rice straw based board is varied between 0.0498 and 0.0543 W m⁻¹ K⁻¹ (Wei *et al.*, 2015).

Influence of Temperature on the Thermal Conduction

The thermal conductivity of rice straw based board was also evaluated by varying the temperature. It is observed that there was a 20% increment in the thermal conductivity of 250 kg m⁻³ board by varying the temperature from 10°C to 50°C. The results have shown strong agreement with the temperature-dependent thermal conductivity of birch wood. The thermal conductivity

of wood-based specimens had demonstrated 14% and 24% increment in the longitudinal and transverse direction respectively in the temperature range of 20–100°C (Suleiman *et al.*, 1999). This is due to the fact that temperature increment enhances the thermal motion of solid molecules. The total thermal conductivity is also dependent on heat transfer due to radiation. Another fact of increment in the temperature-dependent thermal conductivity is the basis of the composition of bio-originated products i.e., ligno-cellulosic materials. At the micro level, the crystallinity of cellulose structure deviated at higher temperature and resulted in loss in their mechanical properties and also altered their ability of heat conduction.

Influence of Moisture on the Thermal Conduction

Besides all other factors, humidity is also an important factor for bio-originated insulation materials. The natural materials are sensitive to moisture but some natural materials like jute, hemp, cork, rice straw have shown excellent result against moisture. The influence of the moisture on the wood-based fiberboard had been investigated by Troppová *et al.* (2015). The thermal conductivity was calculated in the temperature range of –10 to 60°C at different moisture content. It is quite clear in the results that moisture content enhances the thermal conductivity of wood-based composites. Hence a hydrophobic coating would be a great idea to improve the insulation performance of wood-based board.

Mechanical Properties of Building Insulation Materials

Most of the authors devoted to the thermal insulating properties of materials, while very few researchers have shown their concern about the mechanical properties of insulation. Wei *et al.* (2015) have reported the influence of moisture content on the mechanical properties of rice straw based hot pressed board. The relationship between pressing temperature vs. internal bonding strength and modulus of rupture was estimated for coconut husk and bagasse based insulation board. The board was prepared by hot pressing technique without using the artificial binding agent. Modulus of rupture was increased by varying the hot pressing time and temperature. Modulus of rupture was not only dependent on the internal bonding strength of fibers but also act as a function of geometry, orientation and individual strength of fibers. The modulus of elasticity followed the same trend as the modulus of rupture. Most of the specimen was found to behave as an open cell porous structure and follows the power law of density. The bulk moduli of bagasse based insulation board were found to be 102 MPa, 392 MPa and 957 MPa at a density of 250 kg m⁻³, 350 kg m⁻³ and 450 kg m⁻³ respectively. While the moduli of rupture of coconut husk based board were 88 MPa and 365 MPa at 350 kg m⁻³ and 450 kg m⁻³ respectively.

Conclusions

Characterizations of wood and cork based building insulation is an intense area of research nowadays. Environmental protection and energy conservation are the two most prominent areas of exploration due to several regulations and country policies. The optimum thickness of insulating materials depends on the cost of energy consumption and the cost of insulation. The increment in the cost of energy increases the demand for insulation material. The insulating material saves energy utilization by the act as a barrier between system and surroundings. The preparation methodology and several characterizations techniques of wood and cork based composites for building insulation system has been discussed in this article. The effect of density and porosity of specimen is clearly visualized in recent investigations. The high-density wood-based composites range the thermal conductivity between 0.12–0.98 W m⁻¹ K⁻¹, whereas, the wood-based nanocomposites aerogel shows around 0.008–0.040 W m⁻¹ K⁻¹. The influence of moisture and temperature variation plays an important role in the thermal conductivity of wooden composites. Mechanical properties such as bonding strength, modulus of rupture and compression strength depend on the size of particles, density and preparation methodology. This article covers the importance of insulation in the building sector, several primary and secondary characterization etc.

Introduction

The necessity of replacing fossil fuels by renewable energy resources is not deniable. Fossil fuels release carbon dioxide, nitrous oxide, methane, and other pollutants that have greenhouse gas (GHG) effect. GHGs concentrations in the atmosphere have enormously increased during the last century (Metz, 2007). The increasing trend of GHG emissions draws serious negative effects on world climate. Increases in GHG emissions mostly caused by human activities. It is required to decrease GHG emissions to minimize the future climate change. A part of this goal can be achieved by substituting fossil fuels with biofuels. Other motivations to develop renewable energy resources are the wide fluctuations in the oil price as well as the security of energy supply. In addition, local production is a specific feature of bioenergy, which can help rural development.

Biofuels

Biofuels, as fossil fuels substitutes, have the potential of improving the energy security and quality together with reducing the global warming (Chum and Overend, 2001). Biofuels are produced from biomass, e.g., agricultural material, wood, energy crops, organic fraction of municipal solid waste, manure, and algae. In other words, biofuels are produced from recently living biomass as opposed to ancient biomass in fossil fuels. Biofuels are divided to solid, liquid, and gaseous forms and include wood pellets, bioethanol, biodiesel, and biogas. The global biofuels production increased from 37 to 84 million tons oil equivalent from 2007 to 2017, annually. The European Union planned a proportion of 10% for renewable resources in final energy consumption in the transport sector by 2020.

First generation biofuels, which is prepared from food and feed crops containing sugars, starch, and vegetable oils, have been widely investigated to this point. These crops are available in limited quantities, and their use as biofuel substrates make a direct competition between food and fuel. Second-generation biofuels can be produced from different types of non-food biomass, including animal waste and plant residue, which are mostly lignocellulosic biomass. Second-generation biofuels are more favorable than first-generation biofuels because of lower GHG emissions, in addition to being non-food resources (Fig. 1).

The most widely applied biofuel is bioethanol with an approximate portion of 90% of total biofuels consumption, mostly in Brazil, the United States, and some European countries. It can be produced from different substrates, including corn (maize), cereal crops, potatoes, sugar cane, sugar beets, cassava, sorghum, and lignocellulosic materials.

Ethanol can be used alone or as a blend with gasoline for transportation applications. However, it is usually blended with gasoline to increase the octane number of gasoline, improve cold start of the engine, decrease the gasoline consumption, improve engine performance, and reduce air pollution. Ethanol combustion produces carbon dioxide which can be consumed by biomass during the growth cycle. Therefore, there is no net increase in the CO₂ emissions (Wyman, 1994).

Bioethanol Production

Second-generation bioethanol, produced from lignocelluloses, is one of the most promising renewable energy resources and the main topic in this article. Lignocelluloses are mainly composed of cellulose, hemicellulose, and lignin. The lignocellulose cell wall

Fig. 1 Different generation of biofuels.

Fig. 2 Different methods for bioethanol production from lignocelluloses: (A) Separate hydrolysis and fermentation, (B) simultaneous saccharification and fermentation, (C) simultaneous saccharification and co-fermentation, and (D) consolidated bioprocessing.

has a highly complex and compact structure and acts as a barrier to enzymatic/microbial hydrolysis and the following fermentation. Therefore, a substantial pretreatment is essential to make lignocelluloses degradable. Different pretreatments aim at increasing the accessibility of the polysaccharides to hydrolytic enzymes. Discarding pretreatment step, enzymatic hydrolysis can only release less than 20% of the sugars. Comprehensive reviews and book articles have been focused on the pretreatment methods for lignocellulosic substrates (Mood *et al.*, 2013). This topic is not within the purpose of this article; thus, the interested readers can refer to the related references.

Hydrolysis

In hydrolysis stage, polysaccharides are depolymerized and converted into oligosaccharides and monosaccharides. Enzymatic hydrolysis is known as the most effective process to liquefy polysaccharides. Cellulases and hemicellulases are used simultaneously for the hydrolysis of cellulose and hemicellulose, respectively. The conjugated action of these two enzymes yields higher sugar production (Talebnia *et al.*, 2010). Cellulose is converted to glucose and hemicellulose is depolymerized to glucose, galactose, mannose (C6 sugars), as well as xylose and arabinose (C5 sugars). Hydrolysis of lignocelluloses for ethanol production was also presented in the literature (Sun and Cheng, 2002).

Fermentation

The sugar-rich hydrolysate from hydrolysis stage can be fermented by microorganisms to produce ethanol. The theoretical yield of ethanol production is 0.51 g ethanol per kg of glucose (Hamelinck *et al.*, 2005). In the fermentation stage, it is very important that the operational conditions, such as temperature and pH, be maintained in the optimum range for the growth of microorganism (Aditiya *et al.*, 2016). An important factor preventing industrial utilization of lignocelluloses for bioethanol production is the lack of microorganisms able to efficiently ferment (with high yield and high rate) all sugars (both pentoses and hexoses) released during pretreatment and hydrolysis stages.

Different Approaches for Bioethanol Production

Different approaches are used to produce ethanol from lignocelluloses via enzymatic hydrolysis and fermentation, depicted in Fig. 2. Hydrolysis (saccharification) and fermentation of pretreated lignocellulose can be performed at separate reactors or at the same reactor. When hydrolysis and fermentation are performed at separate steps, the process is called separate hydrolysis and fermentation. This approach makes the possibility of performing each step at its optimum conditions. The common

Fig. 3 Production of different biochemical/bioproducts by SSF.

microorganism applied in this approach, *Saccharomyces cerevisiae*, is only able to ferment C6 sugars. Therefore, C5 sugars should be fermented at a separate stage using another microorganism. Also, the hydrolysate needs to be squeezed in this process to be feed to fermentation step, which requires energy and water input. Another approach is simultaneous saccharification and fermentation, which hydrolysis and fermentation are combined in one stage. In this approach, the microorganism consumes glucose as soon as it is produced. Therefore, the inhibitory effect of glucose on enzymatic hydrolysis is reduced. Simultaneous saccharification and fermentation process has other advantages over separate hydrolysis and fermentation, including less energy requirement, lower enzyme need, less contamination potential, and higher ethanol yields (Olofsson *et al.*, 2008). When the microorganism applied in SSF is able to ferment both C6 and C5 sugars, the process is called simultaneous saccharification and co-fermentation. In this process, the inhibitory effect of xylose is also eliminated with its consumption, which leads to the increase of ethanol yield. Consolidated bioprocessing includes the biological conversion of lignocelluloses into bioethanol in a single step without adding enzymes and has been attracted numerous researches in recent years. In consolidated bioprocessing, enzyme production, hydrolysis, and fermentation are performed by a single strain or a group of microorganisms in one step (Olson *et al.*, 2012).

In addition, the process of ethanol production can be performed in submerged or solid-state approaches. When the substrate and microorganisms are floated in free water during the process, it is called submerged fermentation (SmF). And, if the process is performed in the presence of no or only a few free water molecules, it is called solid-state fermentation (SSF). The water content in SmF process is 90%–95%, and some solids are suspended in liquid phase. In contrast, the moisture content in SSF is typically in the range of 12%–70% (Chen, 2013). The SmF is well established, while SSF is still the topic of intensive research in recent years.

Solid-State Fermentation

SSF process is conducted in the absence or near absence of free liquid phase, unlike SmF (Pandey, 2003). However, the presence of enough moisture (usually around 60%) in the system is necessary for microorganisms to grow and metabolize the substrate. In recent decades, SSF in biological processes, specifically in biofuel production, is considered as the least expensive process and the most environmentally friendly (Zhou *et al.*, 2018).

SSF has been used for production of traditional foods and mould-ripened cheese since a long time ago. This method has been widely used for different purposes such as production of secondary metabolites, enzymes, Chinese food, natural flavors, protein-enriched foods, and bioconversion of lignocelluloses (Olofsson *et al.*, 2008), Fig. 3. SSF is commercially applied for some purposes, e.g., bread making, and enzyme and biogas production. However, its application in ethanol production is still in the research phase.

Fig. 4 Different factors affecting ethanol production by SSF.

Influencing Factors on SSF

The selection of microorganism, substrate, and operational conditions are the most influencing factors in SSF, which are explained in this section (Fig. 4).

Microorganism for SSF

The selection of microorganism is one of the most important factors that influences ethanol production through SSF. The desired water activity for the growth of bacteria, yeasts, and fungi in solid-state environment is different. Bacteria and yeast typically grow at water activity values about 0.9 and 0.8, respectively. Whereas, the desired value of water activity for fungi is between 0.6 and 0.7. The microorganisms adapted to environments with lower water activity values are more suitable for SSF. The industrial microorganism for applying in an SSF process of lignocelluloses should have a high ethanol yield and productivity, high resistance to sugars, ethanol, and salts, high specific growth rate, the ability of utilizing different substrates, low nutrition needs, and thermal and shear tolerance. Such a microorganism with all these features is not known in nature. However, the yeast *Saccharomyces cerevisiae* has been successfully applied in industrial scale. Some microorganisms, including *Mucor indicus*, *Zymomonas mobilis*, and Thermotolerant *Issatchenkia orientalis*, has also been studied for SSF ethanol production and showed acceptable ethanol yields.

Some anaerobic bacteria have also the ability to produce ethanol from lignocelluloses, but the process has a very slow rate, low ethanol yield, high production of byproducts, and very low tolerance to ethanol. One of the features of anaerobic bacteria, like *Z. mobilis*, is low production of biomass, and thus converting the majority of carbon source to ethanol. *Z. mobilis* metabolizes glucose to ethanol using the Entner-Doudoroff pathway and shows high ethanol yield and tolerance. However, it could not occupy the position of *S. cerevisiae* in industrial applications until now.

In nature, fungi usually live on moist solid substrates such as wood, roots, seeds, stems, and excrement of animals. Filamentous fungi are thought to be the best options for SSF because of their physiological, biochemical, and enzymological characteristics. These characteristics include hyphal tip growth and high tolerance to high osmotic pressure and low water activity. Therefore, solid-state fermentation offers the greatest potentials with the presence of filamentous fungi (Manan and Webb, 2017).

Moisture content

The moisture content, as one of the most influencing factors on the enzyme stability, microbial growth, and ethanol yield, should remain constant at its optimum value during SSF process. The optimum amount of water for microbial activity of different microorganisms is presented based on the water activity (a_w) of the culture, which indicates the amount of water in the substance. Too low moisture contents lead to the decrease of microbial growth, nutrition diffusion, enzyme resistance, and substrate swelling, and finally result in the process cessation. On the other hand, the high moisture contents of substrate result in agglomeration of particles, decrease in the surface area of substrate, limitations in oxygen transfer, and great decrease in ethanol production. A method to provide enough moisture is adding the desired amount of water during the process. Feeding with saturated air is another common method to avoid substrate drying in designated fermenters. The moisture content in the range of 70%–80% is shown as the optimum value for ethanol production from lignocelluloses by SSF process (Molaverdi et al., 2013).

Microorganism concentration

The initial inoculation is another important parameter that its value should be optimized to improve the rate of ethanol production in SSF. Increasing the inoculation concentration up to a special point increases the ethanol yield. After that point, the ethanol yield decreases because of overusing sugars by microorganisms for their growth and maintenance (Kwon *et al.*, 2011).

Particle size

The particle size of substrate is another factor, influencing ethanol production by SSF. The particle size with effects on the shape, porosity, and accessible surface area of substrate can interfere the rates of heat and mass transfer and microbial growth. Smaller particle size of substrate can increase the initial rate of hydrolysis and degradation by providing larger accessible surface area to the hydrolytic enzymes. However, too small particle size would cause geometric limitations of mycelia growth, and heat and mass transfer limitations, especially for oxygen diffusion, which can be mentioned as steric hindrance. An optimum particle size can provide adequate oxygen diffusion, nutrients accessibility, and mycelia growth. Particle size and the related properties may change during fermentation (Karimi *et al.*, 2014).

Temperature

Each microorganism has an optimum temperature for maximum metabolite production. The microbial activity generates heat, which can be accumulated in bioreactor and leads to the temperature increase due to the heat transfer limitation in SSF. Overheating the bioreactor disturbs the microorganisms' growth, the synthesis of enzymes, and the production of ethanol. Also, overheating in large-scale bioreactors results in moisture loss, which in turn, disturbs the growth of microorganisms. To avoid this problem, design of SSF bioreactors is performed with a focus on maximizing heat transfer. On the other hand, temperature control causes temperature variations, which can produce a large amount of water condensed and dropped back to fermenter, and consequently creates a heterogeneous environment. To maintain the temperature within the ideal range, an air inlet is usually applied to make the system cool. To maintain the required moisture in the system, the loss of moisture by the air outlet must be considered (Nee'nigam and Pandey, 2009).

Mixing

Mixing or agitation can disrupt gradients and improve homogeneity in SSF systems, in addition to helping aeration. However, continuous or severe mixing can disturb the microorganism cells, particularly the mycelium of filamentous fungi. Slow and irregular agitation may be applied to avoid cells damage. However, the mixing of SSF process is not always preferred. Generally, it is suitable when yeasts or bacteria are used, because they are not tightly attached to the substrate (Mitchell *et al.*, 2011; Zhao *et al.*, 2017).

pH

The measurement and control of pH in SSF is too difficult due to the absence of free water, the system heterogeneity, and the lack of pH electrode in the solid media. Using the microorganisms with the ability of growing at wide ranges of pH is usually preferred. Different groups of microorganisms prefer culture environments at different pH values. In general, the favorite environment for bacteria has almost neutral pH, that of fungi and yeasts has poor acidic pH, and actinomycetes mostly prefer basic environment. Applying the usual electrodes for the substrate suspended in water or potentiometric electrodes are available methods for measuring pH value in SSF process (Behera and Ray, 2016).

Advantages and Disadvantages of SSF

Application of SSF instead of SmF offers from several advantages, as listed in Table 1. An important advantage of SSF rather than SmF is its resistance to catabolite repression of enzyme synthesis. Catabolite repression is a system of gene control which causes quick adaptation of microorganism to a preferred carbon and energy resource (mainly glucose). This phenomenon suppresses the metabolism of other carbon resources in the presence of glucose, usually through inhibiting the synthesis of enzymes involved in catabolism of other sugars. Catabolite repression does not occur in SSF even in the presence of 100 gL⁻¹ sugar, whereas severe repression happens in SmF at sugar concentrations higher than 10 gL⁻¹. Some hypotheses were introduced to explain the resistance of SSF to metabolite repression, including the presence of sugar gradients inside the aggregate of microorganisms and changes in sugars permeability of microorganisms grown by SSF (Viniestra-González and Favela-Torres, 2006). This feature can effectively modify the performance of SSF consolidated bioprocessing, since enzyme production happens in the same step of hydrolysis and fermentation.

The interesting point is that most microorganisms, e.g., filamentous fungi and most actinomycetes, naturally live on the wet surfaces, considered as natural SSF (Carlile *et al.*, 1994). Therefore, the natural strains mostly have been adapted to SSF conditions.

In addition, lower water activity in SSF leads to lower demand on sterility (Hölker *et al.*, 2004). Low water content also results in lower probability of contaminations. Downstream processing, including ethanol distillation, is easier and less energy demanding because of the higher concentration of ethanol (Canabarro *et al.*, 2017). One of the main problems in SmF is foam production that prevents oxygen mass transfer, especially in the case of using filamentous fungi. However, foam is not produced in SSF process. Generally, SSF is proved as an economically feasible process (Manan and Webb, 2017). Also,

Table 1 Advantages and disadvantages of SSF process

<i>Advantages</i>	<i>Disadvantages</i>
– Lower catabolite repression	– Existence of temperature gradient
– lower water demand	– Mass and heat transfer limitations
– Less liquid waste production	– Substrate and moisture gradients
– Lower demand for sterility	– Steric hindrance
– No rigorous process control requirement	– Bed caking
– No foam production	– Difficulty in handling solids in reactor
– Absence of anti-foam chemicals	– Difficulty in mixing
– Easier aeration	– Difficulty in pH control
– Higher volumetric productivity	– Difficulty in biomass measurement
– Higher concentration of ethanol	– Difficulty in scale-up
– Lower capital investment	– Lack of kinetic and design data
– Lower operating costs	– Loss of moisture
– Lower energy requirements	
– Lower cost for ethanol recovery	

traditional applications of SSF in food processes shows tremendous potential of this promising process for industrial applications.

Although SSF offers some unique advantages, it undergoes some operational disadvantages which needs further attempts to overcome. Mixing/agitation is a challenge in SSF, as it is difficult or impossible. The absence of mixing can restrict the growth of microorganism due to limited nutrient diffusion and also inhibit the growth of some microorganisms. Also, SSF process suffers from some engineering problems, such as temperature build-up, the presence of gradients in concentrations of substrate, moisture, and products as well as pH, which all are due to the limited mass and heat transfer. Besides, heat, accumulated during the growth and metabolism of microorganism, leads to the moisture loss.

Difficulties in biomass measurement have limited the available information on microbial growth, and kinetics data in SSF. Moreover, the lack of data causes difficulties in scaling up of laboratory results. Another important factor for scaling up a SSF bioreactor is finding the operating conditions that yield constant values of water and energy balances with increasing scale. However, several bioreactors have been recently made to overcome the scaling up problems (Singhania *et al.*, 2009).

Low biomass concentration and low density of mycelia can occur for cellulolytic fungi in SSF of lignocelluloses, which are due to the steric hindrance of the growth of filamentous fungi. The term “steric hindrance” refers to the combined effect of geometric limitations of mycelia growth, especially in substrate pores, mass transfer limitations, and low substrate availability (Laukevics *et al.*, 1985).

Bed caking is another common problem in SSF, which occurs due to the changes in substrate during the fermentation. This phenomenon makes some problems in process control and downstream treatments.

Despite the problems that exist in performing SSF and its scaling up, this process is considered advantageous in competition with SmF.

SSF Bioreactors

Bioreactors are responsible for providing a sealed and proper medium for microorganism to grow and produce ethanol. As it was discussed in Section “SSF Bioreactors”, the optimization and control of influencing factors, including moisture content, temperature, oxygen content, mixing, pH, are very important in SSF bioreactors. Some operating parameters like cooling system, the heat transfer coefficient of fermenter wall, aeration, and oxygen diffusion in gas phase needs careful consideration in the design of SSF bioreactors.

Improper oxygen transfer can often occur in some designs of SSF bioreactor, affecting the moisture content and temperature of medium. An appropriate design of bioreactor leads to high rates of bioreactions, which consequently results in high rates of microorganism growth, substrate consumption, and ethanol synthesis.

To design a special SSF bioreactor for a specific biological process (ethanol production), many parameters, including mixing, moisture gradients, aeration, oxygen transfer, temperature control, stability, reliability, scale-up, and costs, should be considered. Different types of bioreactors have been developed and used for SSF process, and different researchers named them differently. However, Mitchell *et al.* (2002, 2011) classified SSF bioreactors into four groups based on mixing and aeration, Fig. 5:

- *Un aerated and unmixed bioreactors*: In this group of bioreactors, air stream is not blown forcefully through the bed, but it is circulated around the bed, and they have a static or occasionally mixed (e.g., twice a day) bed. Tray bioreactor is another name of this group.
- *Forcefully-aerated bioreactors without mixing*: In these bioreactors, air stream is blown forcefully through the bed, and the bed is static or mixed occasionally (e.g., once a day). *Packed-bed bioreactor* is the typical name of this group.

Fig. 5 Classification ofSSF bioreactors: (A) Tray bioreactor, (B) packed bed, (C) rotating drum, and (D) gas-solid fluidized bioreactors.

- *Unaerated, continuously/intermittently mixed bioreactors*: In this group, air stream is not blown forcefully through the bed, but circulated around it, and the mixing is performed continuously or intermittently with intervals of minutes to hours. Stirred-drum bioreactors and rotating drum bioreactors are two type of bioreactors in this group, having different mechanisms for mixing. This type of bioreactor can be used for batch or continuous operation.
- *Forcefully-aerated, continuously/intermittently mixed bioreactors*: In these bioreactors, air stream is forcefully blown through the bed, and the mixing is performed continuously or intermittently with time intervals of minutes to hours. Selecting continuous or intermittent mixing is dependent to the microorganism sensitivity to shear stress and the physical properties of the substrate. Different designs belong to this group, such as gas-solid fluidized bed bioreactors, stirred-aerated bioreactors, and rocking drum.

Conclusions

Ethanol, the most widely applied biofuel, can be produced through different approaches from various substrates. A promising approach is SSF that has interested many researches during the past few years. It is because of many technical advantages of SSF in comparison with SmF, including less water requirement, higher volumetric productivity, less liquid waste production, easier downstream processing, less capital investment, and less operating costs. SSF has been widely used at industrial scale for other products. However, its application for ethanol production has been recently started and is mostly still performed at laboratory scale. The main challenges of SSF, including mass and heat transfer limitations, can be solved by an appropriate design of bioreactor and are still at development stage.

Nomenclature

Latin symbol

C	Energy constant of GAB model
C_p	Specific heat at constant pressure ($J.kg^{-1}.K^{-1}$)
C_{p0}	Specific heat of dry material at constant pressure ($J.kg^{-1}.K^{-1}$)
C_{p1}	Specific heat of water at constant pressure ($J.kg^{-1}.K^{-1}$)
D_T	Mass (vapor and liquid) transport coefficient associated to a temperature gradient ($m^2.s^{-1}.K^{-1}$)
$D_{T,v}$	Vapor transport coefficient associated to a temperature gradient ($m^2.s^{-1}.K^{-1}$)
D_θ	Mass (vapor and liquid) transport coefficient associated to a moisture content gradient ($m^2.s^{-1}$)
$D_{\theta v}$	Vapor transport coefficient associated to a moisture content gradient ($m^2.s^{-1}$)
E_1	Monolayer enthalpy of adsorption ($kJ.mol^{-1}$)

Greek Symbol

ϕ	Relative humidity (%)
π	Water vapor permeability ($kg.m^{-1}.s^{-1}.Pa^{-1}$)
θ	Moisture volumetric content ($m^3.m^{-3}$)

E_m	Multilayer enthalpy of adsorption ($kJ.mol^{-1}$)
g	Gravity acceleration ($m.s^{-2}$)
h_M	Convective mass transfer coefficient ($m.s^{-1}$)
h_T	Convective heat transfer coefficient ($W.m^{-2}.K^{-1}$)
K	Energy constant of GAB model
Le	Lewis number
L_v	Heat of vaporization ($J.kg^{-1}$)
M_w	Molecular weight ($g.mol^{-1}$)
P_v	Vapor pressure (Pa)
P_{vs}	Saturation pressure of water vapor (Pa)
R	Ideal gas constant ($J.mol^{-1}.K^{-1}$)
T	Temperature (K)
t	Time (s)
w	Moisture content ($kg.kg^{-1}$)
w_m	Monolayer moisture content ($kg.kg^{-1}$)
x	Abscissa (m)

λ	Thermal conductivity ($W.m^{-1}.K^{-1}$)
ρ_l	Mass density of water ($kg.m^{-3}$)
ρ_v	Mass density of water vapor ($kg.m^{-3}$)

Introduction

Temperature and relative humidity are important parameters influencing perceived indoor air quality and human comfort. High moisture levels can damage construction and inhabitant's health. High humidity harms materials, especially in cases of condensation and it helps moulds development increasing allergic risks. The use of various hygroscopic materials is a passive way to moderate indoor humidity levels. The material that adsorbs and desorbs water vapor can be used to moderate the amplitude of indoor relative humidity and therefore to participate in the improvement of the indoor quality and energy saving (Hameury, 2005; Shea *et al.*, 2012; Maalouf *et al.*, 2014; Samri and Moujalled, 2014; Olalekan and Simonson, 2006; Tran Le *et al.*, 2010). The use of vegetable particles (such as flax shives, straw bales, etc.) as building material aggregates is an interesting solution as they are eco-friendly materials and have low embodied energy. Among these vegetable particles, hemp shives have been extensively studied in many researches (Li *et al.*, 2017; Gurlay *et al.*, 2017; Amziane *et al.*, 2016). Hemp shives can be used as particle boards, biodegradable plastics, building materials for thermal and acoustic insulation products (Li *et al.*, 2013; Pantawee *et al.*, 2017), etc. Hemp concrete which is one of these materials is more and more recommended by the eco-builders for its low environmental impact. The physical properties (thermal conductivity, heat capacity, sorption isotherm, water vapor permeability, etc.) of hemp concrete have been measured by many authors (Collet *et al.*, 2008; Rahim *et al.*, 2015) showing that it presents high moisture buffering capacity and a good compromise between insulation and inertia materials.

The knowledge of hygrothermal profile of materials is very important in order to evaluate the performance and the durability of building envelope. For studying the hygrothermal behavior of a hemp concrete wall, a simulation should be done because it is cheaper and able to give more detailed results than a test in situ. For this purpose, many simulation tools have been developed and hygrothermal properties are required for all Heat, Air and Moisture transfer (HAM) models. Many models and simulation tools are represented in the Annex 41 of the International Energy Agency's (Woloszyn and Rode, 2008). For the building envelope, the main difference in HAM-transfer modeling is made by the dimension of represented phenomena and they can be categorized by the

granularity and complexity. Up to now, most hygrothermal tools have used the isothermal sorption curves that express the equilibrium between the moisture content and relative humidity in the representative elementary volume at a constant temperature.

A detailed parametric study of hygrothermal behavior of a wall made of hemp concrete subjected to hygrothermal shocks was carried out and showed that temperature and relative humidity variations in the wall are very sensitive to thermal properties, moisture transport coefficient and sorption isotherm (Tran Le *et al.*, 2014). However, few works studied the effect of temperature dependence of sorption on hygrothermal behavior of building envelopes (Carsten and Clorius, 2004; Poyet and Charles, 2009; Ait Oumeziane, 2014). Concerning hemp concrete, some studies showed a significant difference between numerical and experimental results when neglecting the effect of temperature on the sorption curves (Samri and Moujalled, 2014; Tran Le *et al.*, 2016; Colinart and Glouannec, 2017). In contrast to hemp concrete, a recent study that focuses on the prediction of the evolution of sorption curves with temperature on earthen plasters and compacted earthen samples, concluded that *"if the choice of taking into account the temperature dependency of sorption curves will depend on the required precision, the assumption that $w=w(\varphi)$ seems quite acceptable for moderate variations of temperature"* (Fabbri *et al.*, 2017).

This article aims to study the effect of the temperature-dependent sorption on the prediction of hygrothermal behavior of a hemp building envelope subjected to variations of temperature and relative humidity. First, details for the mathematical physical models are presented to investigate the influence of non-isothermal conditions. The models were elaborated and implemented in the Simulation Problem Analysis and Research Kernel (SPARK), which is adapted to the complex problems. Then, the simulation tools are validated by experimental results obtained from a tested wall conducted in our laboratory, in which the relative humidity and temperature in the middle of the hemp concrete wall were measured for 5 days. After being validated, a parameter sensitivity analysis will be discussed. In the next part, a mathematical model for the coupled heat and moisture transfer in building materials will be presented.

Mathematical Models

Heat and Moisture Transport in Porous Building Materials

Mechanisms of moisture transport in a single porous building material have been extensively studied (Philip and De Vries, 1957; Kunzel, 1995; Mendes *et al.*, 2003). Most of the models have nearly the same origin; the main difference among them is related to assumptions used. In this article, the model that takes into account liquid and vapor moisture transport is used (Mendes *et al.*, 2003). Forms of moisture transport depend on the pore structure as well as on the environmental conditions. The liquid phase is transported by capillarity whereas the vapor phase is due to the gradients of partial vapor pressure. With these considerations, the mass conservation equation becomes:

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial x} \left(D_T \frac{\partial T}{\partial x} \right) + \frac{\partial}{\partial x} \left(D_\theta \frac{\partial \theta}{\partial x} \right) \quad (1)$$

with the following boundary conditions respectively for the external ($x=0$) and internal ($x=L$) surfaces of the wall:

$$-p_l \left(D_T \frac{\partial T}{\partial x} + D_\theta \frac{\partial \theta}{\partial x} \right) \Big|_{x=0,e} = h_{M,e} (p_{v,a,e} - p_{v,s,e}) \quad (2)$$

$$-p_l \left(D_T \frac{\partial T}{\partial x} + D_\theta \frac{\partial \theta}{\partial x} \right) \Big|_{x=L,i} = h_{M,i} (p_{v,s,i} - p_{v,a,i}) \quad (3)$$

where the subscript *a* represent the adjacent air and *s* the solid surface of the material, while the subscripts *e* and *i* correspond respectively to the external and internal neighbouring environment (*a*) or solid surface (*s*).

One dimension of the energy conservation equation with coupled temperature and moisture for a porous media is considered and the effect of the adsorption or desorption heat is added. This final one is greater than the heat of vaporization of free water L_v (J/kg), and the difference is expressed as the net isosteric heat (q_{st}). This value depends on the moisture content. The energy conservation equation is written as:

$$\rho_0 C_{p_m} \frac{\partial T}{\partial t} = \frac{\partial}{\partial x} \left(\lambda \frac{\partial T}{\partial x} \right) + Q_{st} \rho_l \left(\frac{\partial}{\partial x} \left(D_{T,v} \frac{\partial T}{\partial x} \right) + \frac{\partial}{\partial x} \left(D_{\theta,v} \frac{\partial T}{\partial x} \right) \right) \quad (4)$$

where C_{p_m} is the average specific heat which takes into account of the dry material specific heat and the contribution of the specific heat of liquid phase:

$$C_{p_m} = C_{p0} + C_{p,l} \frac{\rho_l}{\rho_0} \theta \quad (5)$$

λ is thermal conductivity depending on moisture content.

Q_{st} is the isosteric heat which can be calculated using Powers and Brownyard (1948):

$$Q_{st} = L_v + \frac{a}{(b + w)^c} \quad (6)$$

where a , b and c are the fitting parameters.

Boundary conditions take into account of convective heat transfer, radiative heat transfer and heat associated to phase changes, as expressed in the right hand side of Eqs. (7) and (8) for the external and internal surfaces respectively.

$$-\lambda \frac{\partial T}{\partial x} - L_v p_l \left(D_{T,v} \frac{\partial T}{\partial x} + D_{\theta,v} \frac{\partial \theta}{\partial x} \right)_{x=0,e} = h_{T,e} (T_{a,e} - T_{s,e}) + L_v h_{M,e} (p_{v,a,e} - p_{v,s,e}) + \Phi_{ray,e} \quad (7)$$

$$-\lambda \frac{\partial T}{\partial x} - L_v p_l \left(D_{T,v} \frac{\partial T}{\partial x} + D_{\theta,v} \frac{\partial \theta}{\partial x} \right) \Big|_{x=L,i} = h_{T,i} (T_{s,i} - T_{a,i}) + L_v h_{M,i} (p_{v,s,i} - p_{v,a,i}) + \Phi_{ray,i} \quad (8)$$

In the case lacking a data base of moisture transport coefficients, simplified models should be used. The use of simplified mathematical models has varying effects on accuracy and has been discussed by Mendes *et al.* (2003). The moisture diffusion coefficient related to moisture content gradient is evaluated as:

$$D_\theta = \pi \frac{P_{vs}(T)}{P_l} \frac{\partial(\varphi)}{\partial \theta} \quad (9)$$

The equations contain several parameters that are themselves function of the state variables. The special interests of the model are the dependencies of moisture content, moisture transport coefficient, thermal conductivity etc., upon the relative humidity and temperature. This makes possible to take into account of the temperature-sorption dependence into the model, which will be presented in the next sub-section.

Effect of Temperature on the Sorption Characteristics

The moisture sorption isotherm of material describes the relationship between relative humidity and moisture content. The knowledge of sorption isotherm of hemp concrete is important to predict its hygrothermal behavior (Carsten and Clorius, 2004; Ait Oumeziane, 2014; Dubois *et al.*, 2016; Tran Le *et al.*, 2016; Colinart and Glouannec, 2017; Costantine *et al.*, 2018; Moujalled *et al.*, 2018). Up to now, many studies have been carried out to measure the general shape of the isothermal sorption characteristic. However, the physics related to the isothermal sorption curves are still disputed. Some studies indicated that the sorption capacity of hygroscopic materials depends on temperature (Carsten and Clorius, 2004; Ait Oumeziane, 2014; Colinart and Glouannec, 2017). Increasing temperature will entail that the moisture content is in equilibrium with a higher relative humidity. Studies of temperature-effect on the hygrothermal behavior of bio-based materials are highly appreciated. Concerning hemp concrete, some studies (Ait Oumeziane, 2014; Tran Le *et al.*, 2016; Colinart and Glouannec, 2017) showed that taking into account of its influence is necessary. In this article, the Guggenheim-Anderson-deBoer (GAB) model (Timmermann, 2003) which is extended from Langmuir and BET theories (Langmuir, 1918; Brunauer *et al.*, 1938) of physical adsorption, is used to describe the relation between sorption characteristics at different temperatures. Using the GAB model has many advantages such as having a viable theoretical background and giving a good description of the sorption behavior of hemp concrete (Andrade *et al.*, 2011; Collet *et al.*, 2008).

The GAB model can be written as follows:

$$w = \frac{w_m C K(\varphi)}{(1 - K(\varphi))(1 + K C(\varphi) - K(\varphi))} \quad (10)$$

where w_m is the monolayer water content value, C and K are energy constants.

To model the temperature-dependent sorption curves using the GAB model, two energy constants C and K are defined as:

$$C = C_0 \exp\left(\frac{E_1 - E_m}{RT}\right) = C_0 \exp\left(\frac{\Delta H_C}{RT}\right) \quad (11)$$

$$K = K_0 \exp\left(\frac{M_w L_v - E_m}{RT}\right) = K_0 \exp\left(\frac{\Delta H_k}{RT}\right) \quad (12)$$

where:

M_w : is the molecular weight [g.mol⁻¹];

R : ideal gas constant [J.mol⁻¹.K⁻¹];

E_1 and E_m are monolayer and multilayer enthalpies of adsorption, respectively.

In order to solve the above-mentioned equation system, the numerical solution is based on the finite difference technique with an implicit scheme. We used the Simulation Problem Analysis and Research Kernel (SPARK) which is especially suited to efficiently solve differential equation systems (Sowell and Haves, 2001; Wurtz *et al.*, 2006; Mendonça *et al.*, 2002; Tran Le *et al.*, 2010).

Experimental Set-Up, Model Validation and Discussions

Experiment Set-Up

To study the hygrothermal behavior of a hemp concrete building envelope (HC wall), an experimental facility has been developed at "Ecole Nationale des Travaux Publics de l'Etat (ENTPE)" in France (see Fig. 1). The experimental setup consists of a climate chamber to simulate outdoor climate conditions, a test wall and hygrothermal sensors for measuring temperature and relative humidity. More details of this facility can be found in Samri (2008). One side of the test wall was subjected to various outdoor conditions of temperature and relative humidity using the climate chamber, while other side of the wall was in contact with the laboratory ambient where temperature and relative humidity are relatively constant. The test wall was instrumented with sensors which are connected to an acquisition system to measure the hygrothermal profiles (see Fig. 1(b)). This study concerns a 30 cm of thick hemp concrete wall and only the results obtained in the middle of the wall (point C) will be presented in order to facilitate the investigation (see Fig. 1(a)).

In this article, the studied wall was subjected to simulated hygrothermal conditions in summer as presented in Fig. 2. It can be seen that the climate conditions in the laboratory are relatively constant while the outdoor temperature and the

Fig. 1 Experimental set-up for studying hygrothermal behavior of the hemp concrete building envelope developed by Samri. Reproduced from Samri, D., 2008. Fig. 2 Hygrothermal conditions in the climate chamber and the laboratory ambient for modeling summer conditions.

outdoor relative humidity (simulated by the climate chamber) vary between 10°C and 40°C; 52% and 97% RH, respectively.

Materials Properties

The hygrothermal properties of hemp concrete measured by Collet (2004); Ait Oumeziane *et al.* (2016); Colinart and Glouannec, (2017) are used for the simulation. The basic hygrothermal data of hemp concrete is given in Table 1. Concerning ΔH_c and ΔH_d , they are set to 4.25 and 0.25 MJ/mol for both adsorption and desorption as recommended by Colinart and Glouannec (2017).

Fig. 3 provides the sorption curves at different temperatures (10°C, 23°C, 40°C and 50°C) and experimental data at 23°C. As one can see from this figure, the moisture content decreases when the temperature increases and the GAB model can predict accurately the sorption curves at 23°C by comparing with the experimental data.

Concerning the isosteric heat Q_{st} (see Eq. 6), the fitting parameters a , b and c ($a=0.697$ J/kg; $b=0.0886$ kg/kg; $c=6.443$) recommended by Ait Oumeziane *et al.* (2016) are used. Fig. 4 shows the variation of the isosteric heat of hemp concrete when the water content varies between 0.01 and 0.2 (kg/kg). It can be observed that the isosteric heat decreases with increasing water content and tends to the latent heat of condensation (L_v); when water content increases from 0.01 to 0.2 kg/kg, Q_{st} decreases from 4.57 to 2.45 MJ/kg.

Model Validation

This article focuses on a more completed model that takes into account the effect of the temperature-dependent sorption characteristics on the hygrothermal response of the hemp concrete building envelope. Two following models are used for the simulation:

- *Isoth* model: Using the isothermal sorption characteristics measured at 23°C in the simulation.
- *Non-Isoth* model: Taking into account the effect of temperature on the sorption curves using the GAB model with the fitting parameters obtained from the literatures (Collet, 2004; Colinart and Glouannec, 2017).

In addition, for each model, three cases have been considered: The adsorption curve, the desorption curve and the mean sorption curve which is obtained from the average of the adsorption and desorption curves.

For both indoor and outdoor surfaces, the heat and mass transfer coefficients are $6 \text{ W.m}^{-2}.\text{K}^{-1}$ and 0.003 m.s^{-1} , respectively. The time step is 240 sec and the wall was discretized into 25 nodes according to recommendations from a sensitive study conducted by Tran Le et al. (2009). Based on initial measured values, the initial relative humidity and temperature in the hemp concrete wall are set to 43% and 21.9°C, respectively.

The simulated temperature and relative humidity at point C obtained from the simulation using the numerical models (*Isoth* and *Non-isoth* models) were compared to those obtained from the experimental measurement and the results are presented in Figs. 5 and 6.

The temperature variations at point C for three cases (adsorption, desorption and mean sorption curves) are very close to each other, only the ones used in the adsorption curve are presented. One can observe that the variation of temperature given by the two

Fig. 7 Effect of initial relative humidity (43%, 46% and 50.5% RH) on the relative humidity profile at point C for the Non-isoth model with adsorption .

numerical models is very similar. Compared to outdoor temperature, temperature in middle of the test wall is dampened and phase shifted. While outdoor temperature varies between 10°C and 40°C, the temperature at point C varies from 20°C to 31.5°C. The time lag (at point C) is around 3.5 h. In summer conditions, the time lag is important and should be increased to shift daily outdoor conditions propagation to the night when outdoor air is colder and night cooling is efficient. The model gives a quite satisfactory prediction of the temperature within the wall, despite the underestimation of the minimum temperature and the overestimation of the maximum temperature.

Regarding the variations of relative humidity, the computed results of the *Isoth* model did not fit the experimental ones (see Fig. 6). In Fig. 6, only the result obtained by the *Isoth* model using the adsorption curve is presented because the ones of three cases (adsorption, desorption and mean sorption curves) are very similar to each other. The relative humidity at point C of the *Isoth* model varies between 43% and 46.3% (so an amplitude of 3.3% RH) while the experimental one varies between 43% and 62.3% (an amplitude of 19.3% RH). This should be explained by the fact that the *Isoth* model neglects the effect of temperature on the moisture sorption capacity of material, in which increasing temperature results in an increase of the relative humidity at a given water content. This explanation is confirmed by the results obtained by the *Non-isoth* model that provides a much better prediction of relative humidity compared to the *Isoth* model (see Fig. 6). Comparing the three cases investigated for this model, the results are dependent on which the sorption curve is used for the simulations. The predicted values calculated with the adsorption curve allow a better prediction of the relative humidity variation than those of the model that uses the average sorption curve or the desorption curve. The predicted relative humidity variations at C are more dampened compared to the experimental ones. Numerically, it varies from 43% RH to 50.9% RH so an amplitude of 7.6% RH of the *Non-isoth* model with adsorption compared to an amplitude of 19.3% of the experiment.

The fact that *Non-isoth* model with adsorption allowed the best prediction compared to the ones obtained by using desorption and mean sorption curves is interesting and in line with the results of some studies focussing on hysteresis effect (Lelièvre et al., 2014; Promis et al., 2018). These studies confirmed that the main adsorption curve is close to the moisture sorption hysteresis in the range of relative humidity in this study.

For this model validation, the initial relative humidity and temperature in the hemp concrete wall are set with respect to initially measured values. Fig. 7 shows the relative humidity variations at point C of the *Non-isoth* model with adsorption when initial relative humidities are 43%, 46% and 50.5%. As expected, the initial conditions have a significant effect on the relative humidity profile at point C because the test was only run for a short time. Increasing initial value of RH results in an increase of the relative humidity value at point C. This conclusion is in accordance with a study performed by Osanyintola et al. (2006) showing that the hygric performance of plywood depends on the initial conditions of relative humidity. Note that moisture transport is slow and consequently this effect should be neglected for a test which is run for a very long time. Concerning the effect on temperature variations at point C, it is very small and not presented here.

Indeed, under the hygrothermal conditions of this study, the *Non-isoth* model showed much better performance compared to the *Isoth* model. However, some discrepancies between predicted and measured values were still observed. This difference should be due to uncertainties of fitting parameters of the GAB model and it will be discussed in the following subsection.

Effect of Energy Constant K on the Hygrothermal Behavior of Hemp Concrete

One of the reasons to explain the discrepancies which still remain between predicted and measured relative humidity within the hemp concrete wall is the non-homogeneous properties and the difference between actual hygrothermal properties and the ones used as input data in the simulation due to the manufacturing process itself. Due to the difficulty or impossibility of verifying

actual properties of the test hemp concrete wall, the validated numerical model is a powerful tool that can be used to overcome this limitation by doing a sensitivity study.

It is noticed that the BET model can predict only the sorption of hemp concrete when relative humidity is lower than 50%. To overcome this limitation, the GAB model is used for describing the sorption isotherm of hemp concrete. When K of the GAB model is equal to 1, the GAB model becomes the BET model. Therefore, to facilitate the investigation, this sub-section focuses only on the effect of energy constant K of the *Non-isoth* model with adsorption curve on the prediction of hygrothermal profile of the hemp concrete building envelope by considering three values of K at 23°C: 0.8 (reference case), 0.6 and 0.5.

Concerning the temperature profiles at point C, they are not depicted and presented here because the results obtained for three cases (reference case, $K_{23^\circ\text{C}}=0.6$ and $K_{23^\circ\text{C}}=0.5$) are very close to each other. The result confirmed that the effect of K value on temperature profile at point C is very small. Regarding the relative humidity profile, the result is presented in Fig. 8. One can observe that the energy constant K has a significant influence on the hygric behavior of the hemp concrete wall. The results obtained by the model with $K_{23^\circ\text{C}}=0.5$ are in good agreement with the experimental results. This energy constant value gives a satisfactory prediction of relative humidity within the tested wall. The maximum difference between the computed values for the

Fig. 8 Variations of relative humidity at point C obtained from numerical models and measurement.

Fig. 9 Predicted relative humidity (Non-isoth model), measured temperature and relative humidity variations measured at point C.

model with adsorption curve and the experimental ones is 3% RH. This value is small compared to the accuracy of sensor inserted in the tested wall, which is $\pm 1.5\%$ of RH.

Based on the obtained results, it can be concluded that it is necessary to take into account the non-isothermal conditions on the sorption curves to predict the hygrothermal behavior of a hemp concrete building envelope subjected to the dynamic conditions of temperature and relative humidity. For better prediction, the parameter $K_{23^\circ\text{C}}$ can be empirically determined and justified using experimental data.

Correlation Between Local Temperature and Relative Humidity Variations in the Test Wall

The predicted relative humidity (*Non-isoth* model with adsorption curve: reference case and the case $K_{23^\circ\text{C}}=0.5$), the measured temperature and relative humidity variations at point C are presented together in Fig. 9. Note that similar behavior for both RH and T profiles is observed. Due to the temperature dependence of the sorption isotherm, relative humidity profile in the hemp building concrete wall is strongly correlated to the local temperature variations. This conclusion is in accordance with the experimental studies carried out by Colinart and Glouannec (2017).

Conclusions

This article presents the development and the use of a numerical model that takes into account of the temperature dependency of the moisture sorption characteristics on the hygrothermal response of a hemp concrete building envelope under dynamic conditions of temperature and relative humidity. Two models named the *Isoth* and the *Non-isoth* have been presented and implemented in the simulation environment SPARK which is suited to solve efficiently the differential equation systems. For each model, three cases that use adsorption or desorption or mean sorption curves have been considered. In addition, to validate the proposed models, an experimental facility has been developed. These results obtained in this study are useful in experimental design and HAM-tools development. With respect to the comparison of measured and modelled temperature and relative humidity profiles in the test wall, the following conclusions are drawn:

- Temperature in the middle of the hemp concrete wall is dampened and phase shifted compared to outdoor temperature.
- Taking the influence of temperature on the sorption curves into account is necessary to predict the hygrothermal behavior of the hemp concrete wall.
- Initial conditions have a significant effect on the relative humidity profile at point C in this study (short-time test).
- Both the *Isoth* and the *Non-isoth* models can be used for predicting the variation of temperature. However, only the *Non-isoth* model is adapted to study the variation of the relative humidity. In addition, this study confirmed that the use of adsorption curve is recommended because it is close to the moisture hysteresis curves.
- Relative humidity profile in the hemp concrete wall is strongly correlated to the local temperature variations. The correlation can be determined from the sorption curves at different temperatures.
- Predicted values exhibit smaller relative humidity fluctuations than the measured values. This deviation of the modeling may be explained by fitting parameters used for the GAB model and can be remedied by changing $K_{23^\circ\text{C}}$ value which can be easily justified by experimental data.

Introduction

Nowadays timber buildings are present worldwide and their construction market is growing, because the use of sustainable materials is encouraged both from governments and from public opinion. CO₂ is stored, renewable and environmentally friendly raw materials are used and commonly a very good thermal insulation is provided. Timber elements are produced within industry plants where costs are optimized in advance and where very little waste is produced, according to Kyoto protocol purposes.

Ramage *et al.* (2017) demonstrated how wood for construction is one of the many forest products around the world. It is understood that timber has very good mechanical properties such as high strength to weight ratio, a good service life and high specific heat values. For this reason, gradually the edifices are moving from one or two floors to six or seven multi-story. Furthermore, wastes from wood modification and transformation could become secondary products like chipboards, sand sawdust panels, biomass for conversion or gasification and so on.

Additionally, the introduction of environmental certifications of buildings, requiring high energy savings, high standards of indoor comfort and large usage of ecofriendly materials, raise the need of timber building diffusion.

Wood could be used for almost every requirement, from structural beams to containers, from thermal and acoustic insulation panels to component elements. It could be used for precast products, meaning high repeatability of performances and characteristics.

As an example, CAD-CAM technologies used for the building production permit a wide range of possibility including traditional or new and complex architectural shapes, concepts and tendencies. For every product, the final CE certifications are needed, to ensure its quality.

As a matter of fact, every building component could be made of wood parts, ensuring the same final performances of other materials like metals or plastics. Granzotto *et al.* (2017) clearly demonstrated that timber windows frames could provide same thermal and acoustic insulation properties in comparison with other materials. The research, based on more than 45 laboratory tests, highlighted that no single windows element could define alone final performances, but all constituents participate to final insulation effect. The windows thermal transmittance is the result of the superposition of all single contributions and the frame material is just a link in the chain.

On the other hand, acoustic insulation has shown a full dependence on single parameters, such as PolyVinylButyral for coincidence reduction, overall glass and gas gap(s) thickness to improve middle and, in some case, low frequencies insulation, but no correlation between material frame composition was found.

Both thermal and acoustic best performances can be obtained with all available material frames. So when choosing the best one, wood is the less environmental impactful, with higher insulation values.

On a building scale, wood could provide very good specific heat values, suitable for the insulation from hot climate, but insufficient protection from cold ones.

From the acoustic point of view, Caniato *et al.* (2017a) demonstrated how performances are not always at the top range. For example, impact noise in timber constructions is the most common cause of complaint on the part of inhabitants because in this kind of lightweight buildings the usual impact reduction methods would not properly work.

Technological diversity distinguishing wooden constructions (frame, cross laminated timber, etc.) makes homogenization of forecasting calculation methods more difficult compared to traditional massive buildings (concrete, masonry, etc). Furthermore, applying the same prediction methods or analysis used for heavy weight constructions could lead to misleading results. Nevertheless, prediction methods developed for traditional structures are frequently applied to wooden ones, which is obviously questionable. How many types of wooden structure have been studied? How many of them accurately and satisfactorily?

In this work, energy and acoustic performances of timber in building are described, focusing on thermal and acoustic insulation.

A graphical summary of possible structures is summarized in Table 1. There are three main categories grouping different structures as follows:

- type A: wood structure not included in plaster or fiber board;
- type B: glulam beams with boards screwed on top;
- type C: homogenous wooden structure.

Table 1 Types of lightweight bare partitions included in literature

Code	Description	Scheme
A	Timber-concrete floor. It consists of timber structure with an additional layer of concrete on top of it	
B	Particle or gypsum board on top of wooden glulam beams with screw attaching the boards to the beams. Fibrous layers between beams is often present. These structures could be both walls and floors	
C	Cross laminated timber These structures could be both walls and floors	

Energy Performance of Timber Envelope and Layer

Timber structures could be personalized for every necessity since the precast process ensure the application of different layers and different thicknesses. The most used are rockwool, wood, paper or cellulose waste, and wood wool. Often, a combination of them is used in order to better adapt to diverse climate.

Since type A (Table 1) is only used for internal floors, type B and type C (or a combination of them) are the only possible solutions for vertical walls.

Glulam technology provides the best possibility of potential combinations with different materials and layers, because gaps between beams leave hollow spaces, which could be filled either with panels or by insufflated flakes or particles (Fig. 1). Nevertheless, beams provide thermal bridges, so an additional layer is needed in order to limit this problem. Usually this last stratum is composed by wood wool in order to enhance impact and hot climate insulation performance, whether the inner one is usually softer and lighter, suitable for the cold weather.

For opaque components, transmittance U and periodic transmittance Y_{ie} are the main significant parameters; the first one is described by Eq. (1):

$$U = \frac{1}{\frac{1}{h_e} + \sum_{i=1}^n \frac{d_i}{\lambda_i} + \frac{1}{h_i}} \quad (1)$$

where d_i is the thickness of the layer [m], λ_i is the thermal rated heat conductivity of the material [W/m K], h_e is the heat exchange surface coefficient of the external surface [W/m² K] and h_i is the heat exchange surface coefficient of the internal surface [W/m² K].

This property identifies the thermal insulation from cold external environment in a static condition. The second one is used in order to evaluate the protection from hot climate since in this case the outer temperature could vary a lot during the day.

In case of inhomogeneous structures (e.g., type B), as a first approximation it can be taken into account the percentage of wooden beams in respect with the insulating material laid in the hollow spaces. Since structural elements acts as thermal bridges compared to insulating material, their influence should be considered in final transmittance results (Fig. 2).

In Table 2, beam influence (glulam) on final transmittance value is reported. In the first step, the standard beam dimension of glulam external wall construction (Fig. 3) is calculated (6 cm × 16 cm) and increased by 20%, 50% and 100%. In the second, an external insulating layer constituted by wood wool of 6 cm thickness is applied. It is evident how it reduces the thermal bridge caused by beams.

Fig. 1 Glulam external wall production with cellulose fiber insufflation.

Fig. 2 Wooden beam thermal bridge within glulam structure.

Table 2 Influence of the beam width on final transmittance values

	$U_{first\ step} [W/m^2\ K]$	$U_{second\ step} [W/m^2\ K]$
Standard	0.29	0.20
Standard + 20%	0.30	0.20
Standard + 50%	0.32	0.21
Standard + 100%	0.35	0.22

Fig. 3 External glulam beam construction (a) and beam scheme (b).

The calculation of the periodic transmittance Y_{ie} of a non-homogenous structure is not an easy task, because it depends on thermal conductivity, thickness, specific heat and density of all materials constituting the partition and on the external force (heat flux).

The analytical model is based on transfer matrix solutions combining the described parameters. Since the first hypothesis is that the external temperature is sinusoidal, the solution will be a complex number. For this reason the general numerical model is reported in Eq. (2) (source: ISO 13786:2017):

Table 3 Thermal proprieties of common construction materials

Material type	Conductivity [W/m K]	Specific heat [J/Kg K]	Density [kg/m ³]
Masonry	0.78	940	1700
Concrete	1.6	1000	2300
Wood wool	0.044	2100	200
Rock wool	0.038	840	175
EPS	0.036	1480	35

Table 4 Periodic transmittance and time shift variation for bare structures (20 cm) and additional layers (10 cm)

Material type	Periodic transmittance [W/m ² K]	Time shift [h]
Masonry	1.27	6.5
Masonry + EPS	0.06	8.92
Masonry + wood wool	0.05	12.04
Wood	0.11	12.31
Wood + EPS	0.01	15.48
Wood + wood wool	0.01	16.10

Table 5 Comparison of time shift value within glulam structure of the same thickness (16 cm)

Structure description	Periodic transmittance [W/m ² K]	Time shift [h]
Beam portion	0.24	9.46
Thermal insulator portion	0.21	3.2

$$\begin{pmatrix} \vartheta_2 \\ q_2 \end{pmatrix} = \begin{pmatrix} Z_{11} & Z_{12} \\ Z_{21} & Z_{22} \end{pmatrix} \cdot \begin{pmatrix} \vartheta_1 \\ q_1 \end{pmatrix} \quad (2)$$

The periodic transmittance Y_{ie} is the inverse of the Z_{12} term as reported in Eq. (3) (source: ISO 13786:2017):

$$Y_{ie} = -\frac{1}{Z_{12}} \quad (3)$$

The argument normalized on the time period of Z_{12} represent the time shift imposed by the materials at the sinusoidal external heat as reported in Eq. (4) (source: ISO 13786:2017):

$$(\varphi) = \frac{T}{2\pi} \arg\left(\frac{1}{Z_{12}}\right) \quad (4)$$

where T is time within the sinusoidal variation is present [s].

As a matter of fact, insulation from hot climate will strongly depend on density and on specific heat (comparing materials with same thickness) since this two parameters strongly influence the reactive properties layers.

Wood and wood products have very high specific heat compared to tradition heavyweight materials (masonry, concrete) and lightweight insulators (EPS, XPS, rock wool etc.). They are very useful to rise time shift and periodic transmittance values. In Table 3 A comparison between thermal proprieties of common construction materials is provide and in Table 4 standard construction with additional wooden or non-wooden layers are reported.

Wood products provide higher time shift and lower periodic transmittance values compared to masonry and EPS. The difference is bigger on the traditional heavyweight structures, because no wood product is present in the bare structure.

On the other hand, for periodic structure (glulam) no calculation is possible because of the non-static approach of this phenomenon.

As a matter of fact, the timber beams provide better time shift value compared to thermal insulator as reported in Table 5.

In order to determine the external and internal temperatures, the only possibility, as described by Pernigotto *et al.* (2015) and Pajek *et al.* (2017), is to perform simulations and laboratory experiments; these results could then be used to calculate the correct value of periodic transmittance.

Acoustic Performance

Acoustic performances of timber in buildings could be divided into two main items: airborne sound insulation and impact noise reduction. As a matter of fact, both of them are analyzed at present and every years many researchers and technicians write several papers on these topics. As highlighted by [Simmons et al. \(2011\)](#) and by [Ljunggren et al. \(2014\)](#), noise inside a wooden construction is one of the most complained issue since both users and designers at first steps of planning and construction do not pay attention to this topic.

After an international subjective survey performed by [Caniato et al. \(2017a\)](#), sent to both designers and lay people, it could be concluded that acoustic design and acoustic final performances are the less considered issue but the first cause of indoor discomfort. This could be essentially explained by two alternative scenarios. On one hand, the acoustic insulation is related to wood. On the other hand, since timber buildings are felt like the stereotype of perfect constructions where to live in, it is believed that the whole wall layering could provide some kind of “standard protection”.

In the next paragraphs a dissertation on recent researches is reported and divided into two parts: impact noise and airborne noise.

Impact Noise

The impact noise depends on two independent parameters: impact noise level of the bare floor and sound reduction provided by the chosen insulating technology (floating floor, resilient layers, suspended ceiling)

according to [Eq. \(5\)](#):

$$L_{n,w} = L_{n,w,eq} - \Delta L_w(\text{dB}) \quad (5)$$

where $L_{n,w}$ is the resulting impact noise (dB), $L_{n,w,eq}$ is the impact noise of the bare floor (dB), ΔL_w is the impact sound pressure level reduction (dB).

It is evident that the bare floor acts as starting point and so the type of partitions is the primary source. In timber structures there are many different technologies.

The A technology (Ref. [Table 1](#)) is widely studied and used in Mediterranean countries. [Bettarello et al. \(2010\)](#), performed on field measurement of bare floors, providing an empirical model ([Eqs. \(6\) and \(7\)](#)) describing the frequency trend of the bare floor impact noise.

$$L_{n,eq,avg} = 10.4 \log(f) + 50(\text{dB}) \text{ for } f < 1600 \text{ Hz} \quad (6)$$

$$L_{n,eq,avg} = -6.1 \log(f) + 129(\text{dB}) \text{ for } f > 1600 \text{ Hz} \quad (7)$$

The B technology is the most studied and presents a great number of variants. Since this type of construction performances could be influenced by many parameters such as dimensions and periodicity of the beams, presence, thickness and density of sound absorbing materials in void spaces, stiffness, thickness and number of upper and lower layers etc., parameter studies were carried out by [Brunskog and Hammer \(2003\)](#), in order to determine single components influence. The conclusions report the following considerations:

- Sound absorbing material (with different flow resistivity) in void spaces reduces the impact noise for frequency above 250 Hz,
- Different mass of upper and lower layers provide better performances than a single heavy one,
- Periodic beams displacement influences low frequency range,
- Sound absorbing material could represent up to 15 dB reduction.

The most interesting aspect is that the low frequency effect is caused by the structure itself and it does not significantly vary if big changes (high density added layer, very thick suspended ceilings, etc.) are not applied on it. On the other hand, the wooden structures could better insulate in middle and high frequency range than the heavy weight ones.

Laboratory measurements of glulam floor are very few and not always available. For this reason field measurements could provide missing information about the frequency behavior of the bare floor and the influence of the floating floor and the suspended ceiling as impact noise reduction technologies.

Tests were performed in a three – story construction where floors were tested by [Caniato et al. \(2017c\)](#), on different receiving rooms ([Fig. 4](#)). Panels were constituted of glulam beams (18 cm thickness) connected with wooden chipboard screwed on top of them (2.2 cm thickness), mineral wool between them (10 cm thickness, 55 kg/m³ density) and laterally fastened with wooden closures ([Fig. 5](#)). These panels were laid in order to match the external border, so it was possible to find an air gap between them. This was filled using high sound insulation foam.

Different bare floors results are very similar due to industrial production, so only average final values are worthy of being presented. In [Fig. 6](#) the bare floor impact noise trend is reported both without and with insulating foam inserted inside the air gap between panels. The green trend reports the impact noise level of the separated panels while the red curve represents the impact sound of the sealed panels. It is evident how the insertion makes the pieces work together, thus providing more energy (more excited area) at low frequencies.

After these steps, a first floating floor was posed by the authors using the following layers ([Fig. 7](#)), where s' is the apparent dynamic stiffness per unit area, d the thickness and m' is the mass per unit area of the massive slab:

- Recycled cotton waste resilient layer ($s' = 32 \text{ MN/m}^3$, $d = 8 \text{ mm}$),
- Marble powder (5 cm) in honeycomb paper panels ($m' = 45 \text{ kg/m}^2$).

Then a second floating floor was laid upon the first one using the following coatings (**Fig. 8**):

- Recycled cotton waste resilient layer ($s' = 32 \text{ MN/m}^3$, $d = 8 \text{ mm}$),
- Two gypsum fiberboards (2.5 cm, $m' = 35 \text{ kg/m}^2$).

Impact noise tests using an ISO tapping machine were carried out (**Fig. 9**) and the influence of these sound reduction solutions is reported in **Fig. 10**. The red line represents the bare floor trend, whether the light blue and purple lines highlights the impact noise reduction provided by the two floating floor layers. The contribution offered by these technologies is evident from 80 Hz.

Table 7 Floating floor effect on same thickness different bare floor technologies using frequency Cremer's relation. Frequency trend calculation

	Mass per unit area [kg/m ²]	Measured Normalized Impact sound pressure index of bare floor $L'_{n,w}$ (dB)	Predicted Normalized Impact sound pressure index reduction of floating floor $\Delta L_{n,w}$ (dB)
Glulam	130	76	14
Concrete	600	81	33
Beam and pot	340	87	41

Source: Caniato, M., Bettarello, F., Patrizio, F., *et al.*, 2017c. Impact sound of timber floors in sustainable buildings. Building and Environment 120, 110–122. Available at: <http://dx.doi.org/10.1016/j.buildenv.2017.05.015>.

Afterwards, a screwed ceiling was posed. This setup implies an additional plasterboard (1 cm thick) underneath the timber floor. It was screwed on wooden beam (50 mm thick) with a resulting air gap of 50 mm. In Fig. 11 the influence of the screwed ceiling is reported. In comparison with Fig. 10, it is here evidenced how the screwed ceiling worsen the situation at middle frequencies (purple line), because of the rigid connections.

The worsening caused by the presence of this element is evident. At around 100 Hz its resonance frequency increases the impact noise, according to Eq. (8):

$$f_0 = \frac{60}{\sqrt{\frac{m'}{d}}} [\text{Hz}] \quad (8)$$

where m' is the mass per unit area [kg/m²] of the plasterboard (6.5 kg/m²) and d is the distance (0.05 m) from the floor structure [m].

In order to reduce this effect, the air gap was filled with mineral wool. This operation slightly lowered the middle frequencies, but did not change the resonance influence on the impact noise.

For glulam beams with top boards, in Table 6 the comparison between ISO 12354-2 normalized impact sound pressure index models and measured values is shown. Presented results were calculated using the average of all tests. In order to compare results with predicted ones, Eq. (9) is used to forecast final values

$$\Delta L_{nw, \text{single number}} = 30 \cdot \log(500/f_0) + 3(\text{dB}) \quad (9)$$

where f_0 is the resonance frequency of the floating floor.

It is clear that the relation is not applicable with timber structures since the bare floors are not of infinite mass in comparison with the floating layers. The difference in mass is reduced ($m'_{\text{bare floor}} = 130 \text{ kg/m}^2$ whether $m'_{\text{overall floating floor}} = 80 \text{ kg/m}^2$) in comparison with a concrete bare floor ($m'_{\text{concrete}} = 600 \text{ kg/m}^2$) or beam and pot ($m'_{\text{beam and pot}} = 340 \text{ kg/m}^2$). The focus is the impact of the traditional floating floor; since the flanking transmission values are constant from bare floor to covered floor, the measured final outcomes are influenced only by the additional floating layer.

In Table 7 A comparison of the sound reduction index of an ideal floating floor, used as example, on different structures is presented, using the frequency of Cremer's relation (Cremer, 1942).

The floating floor is composed of a high density coating (90 kg/m², 50 mm thickness) and a resilient layer ($s' = 16 \text{ MN/m}^3$).

Here, it is evident how the same impact sound reduction solution provides very diverse performance, depending on the type of bare horizontal partition. This result depends on the different distribution of the exciting energy coming from the ISO tapping machine and on the specific limit of floating floor technology: low frequency reduction.

The cross-laminated timber (CLT – Type C) panels are constituted of thin beams or planks laid on the top of each other and high pressure glued in order to form a solid uniform board. Therefore, the horizontal (as well as vertical) partitions seem to behave like homogenous slab. Very few studies are present in literature for this kind of structure. Nevertheless, this technology is commonly used in Europe, North America, Australia, New Zealand, etc.

**Fig. 15** Average frequency trends for impact noise, calculated linear regression and dispersion of individual data. Source: Caniato, M., Bettarello, F., Patrizio, F., *et al.*, 2017c. Impact sound of timber floors in sustainable buildings. Building and Environment 120, 110–122. Available at: <http://dx.doi.org/10.1016/j.buildenv.2017.05.015>.

Laboratory tests show the effect of the bare slab reacting to heavyweight impact noise (ISO tapping machine) highlighting the typical “bell-like” frequency trend on middle high frequencies (Fig. 12). The red and blue lines represents different bare floor impact noises with respectively 135 mm and 175 mm thickness. It is evident how the two trends are very similar in the frequency domain; it could be concluded that only the thickness parameter has an influence on final results.

In order to understand if the real acoustic behavior was similar, field measurements were carried out in 16 different bare floors (Figs. 13 and 14).

The increase in frequency at about 2500 Hz could be ascribed to the resonance caused by the ISO tapping machine laid directly on the wooden floor.

In order to compare only single index results, the weighted sound reduction index $L'_{n, w}$ determined by ISO 717-2 method as well as $C_{l, 50-2500}$ factor were calculated (Table 8). It is possible to understand once more that the single number differences are caused by low frequency range.

Linear regression was calculated in order to obtain a possible predicting equation of the impact noise of bare floor.

The mean value of the frequency spectrum trend can be represented with the following equations:

$$L_{n,eq,avg} = -0.15(f) + 77.7(\text{dB}) \text{ for } 50 < f < 80\text{Hz} \quad (10)$$

$$L_{n,eq,avg} = 7.26\log(f) + 35.6(\text{dB}) \text{ for } 100 < f < 630\text{Hz} \quad (11)$$

$$L_{n,eq,avg} = -0.006(f) + 84.4(\text{dB}) \text{ for } 800 < f < 5000\text{Hz} \quad (12)$$

The calculated linear regression coefficient is $R^2=0.99$ for Eq. (10), $R^2=0.89$ for Eq. (11) and $R^2=0.97$ for Eq. (12) and represented in Fig. 15 where 95% of the measured values are situated inside the yellow lined zone.

From the single index point of view, in Table 9, the normalized impact sound pressure index values, calculated according to ISO 12354-2 are described. The first line reports the single index value calculated using ISO 717-2 methods; for the 250 mm bare floor the frequency trend provided by Eqs. (8–10) was used for calculation. No flanking transmissions were taken into account since the L_{nw} parameter was analyzed (laboratory tests).

Table 10 Result summary of airborne laboratory test on glulam partitions

Description	R_w (dB)
(1) Single leaf wall with wooden structure (140 mm thickness), rock wool between beams (140 mm thickness), external wooden chipboards (15 mm thickness)	39
(2) Single leaf wall with wooden structure (140 mm thickness), rock wool between beams (140 mm thickness), external wooden fiberboards (15 mm thickness)	44
(3) Single leaf wall with wooden structure (140 mm thickness), rock wool between beams (140 mm thickness), external wooden fiberboards (15 mm thickness). Additional layer constituted by mineral wool (40 mm thickness) and external fiberboard (15 mm thickness)	48
(4) Vertical wall with double timber structure containing rock wool. Air gap filled with rock wall between the structures, inner wooden chipboards (10 mm thickness) and external single plasterboard	55
(5) Single leaf wall with wooden structure (140 mm thickness), rock wool between beams (140 mm thickness), external double fiberboards (15 + 15 mm thickness). Additional separated layer constituted by rock wool (40 mm thickness) and external fiberboard	62
(6) Single leaf wall with wooden structure (140 mm thickness), rock wool between beams (140 mm thickness), external double fiberboards (15 + 15 mm thickness). Double additional separated layer constituted by rock wool (40 mm thickness) and double external fiberboard	65

It is evident that the standard method does not provide reliable results. In fact it is suggested for homogeneous bare concrete floor with a mass per unit area $100 \text{ kg/m}^2 < m' < 600 \text{ kg/m}^2$. The provided results differ from the measured values up to 10.5 dB. Nevertheless, since this is the only available method, a correction is proposed according to Eq. (13):

$$L_{n,w,eq,corrected} = 134.5 - 25 \cdot \log(m') \text{ (dB)} \quad (13)$$

where m' is the mass per unit area [kg/m^2] of the CLT floor. Using this method, the measured and predicted results agree very well.

Airborne Sound Insulation

For A typology, laboratory tests show how for the bare structure the mass law (Eq. (13)) could be very useful to predict final single index airborne sound insulation value. Furthermore, the addition of a suspend ceiling could be easily calculated and predicted using Eqs. (14) and (15):

$$R_w = 20 \log(m') \quad (14)$$

$$\Delta R_w = 73 - \frac{R_{w,m1}}{2} - 20 \log(f_0) \quad (15)$$

where $R_{w,m1}$ is the sound insulation index of the concrete slab (dB), m' is the mass of the concrete slab [kg/m^2], and f_0 is the resonance frequency of the system [Hz], which can be calculated using Eq. (16):

$$f_0 = 160 \sqrt{\frac{0.1}{d} \left(\frac{1}{m'} + \frac{1}{m''} \right)} \quad (16)$$

Where m'' is the mass of the additional layer [kg/m^2].

For the B typology the airborne sound insulation is generally less investigated than the impact sound pressure level reduction.

Comparing the same structure, the influence of the external massive layer does influence final sound insulation. This final material could vary from wooden chipboard (30 kg/m^2) to plaster or fiber board (from 45 to 50 kg/m^2). As a consequence, sound insulation index could vary between 39 and 45 dB for a traditional 16 cm thickness vertical wall.

As a matter of fact, 7.5 cm plasterboard walls provide sound insulation values from 46 dB to 47 dB. This is due to the fact that timber junctions transmit the airborne sound through the partition, while the steel does not. In order to raise final wooden partitions performances, it would be necessary either to add a double leaf external additional layer ($R'_w > 53 \text{ dB}$) or to split the wall in to two different and separated structures ($R'_w > 55 \text{ dB}$).

Fig. 16 Typical frequency trend of a double structured vertical partition with fibrous material in the middle air gap.

Table 11 R_w values obtained using mass law method and laboratory measurement

Description	Mass law (dB)	Measured R_w (dB)
CLT floor. 175 mm thickness	40.1	39
CLT floor. 135 mm thickness	38.2	39

If the external layers are fixed, the influence of additional inner massive panels (wooden chipboards, plaster or fiber boards) or the insertion of additional fonoabsorbing layer between the two structures will rise the sound insulation performances. A typical frequency trend of a double structured vertical partition with fibrous material in the middle air gap is reported in Fig. 16 where the resonance (63 Hz) and coincidence (3150 Hz) are highlighted. As a matter of fact, even if at middle and high frequency range the partition performance is high, in the low range (<250 Hz) sound insulation values are far from being suitable for a good noise protection.

In order to determine the influence of single parameter on this kind of construction, a very complete work was conducted by Quint *et al.* (2006), where an in-depth laboratory measurement campaign was performed. Starting from the bare partition, it could be concluded that the additional layer could or could not have a real influence on final performances. Results may be summarized as in Table 10.

For C typology, the bare CLT airborne sound insulation performances are not focus of particular studies or researches since, as type A, final values depend only on the mass and thickness of the partition (Eq. (13)). The model agrees with the provided measurement, as highlighted in Table 11.

Conclusions

The use of timber in buildings is described and critically analyzed. Energy and acoustic performances of timber in constructions were described, focusing on thermal and acoustic insulation. Three main typologies of structures were studied: (i) Timber concrete floors, (ii) glulam and (iii) crosslam walls and floors.

Thermal and periodic transmittance numerical models were depicted and adapted for timber structures, focusing on periodic structures (glulam) and homogeneous ones (crosslam). Results evidenced how the influence of beams width in glulam constructions leads to thermal bridges and worsens the overall thermal insulation up to 18%. The use of an external insulating layer could solve the problem limiting the energy transmission at about 2%. On the other hand, wood products like wood fibers provide up to 100% higher specific heat value compared to rockwool or masonry, demonstrating how their use is to prefer in term of external hot climate insulation.

Airborne and impact sound insulation were approached either by field and laboratory measurements of bear constructions. Numerical models were presented and deeply analyzed highlighting the difference between traditional heavyweight and timber

constructions. New equations and simulation-based approaches were presented and validated. For timber concrete buildings, the new formula show how medium low frequencies rises up to 30% in comparison of concrete structures. For glulam structures, parameters studies report that sound absorbing material (with different flow resistivity) in void spaces reduces the impact noise for frequency above 250 Hz sound absorbing and could represent up to 15 dB reduction. Furthermore, the use of floating floor(s) may provide up to 16 dB extra reduction, while the use of rigid fastened suspended ceiling will worsen the results in dependence of its resonance frequency.

The crosslam technologies provided a “bell-like” frequency trend centered on middle high frequencies and a dependency of the floor thickness was highlighted as the more important parameter.

Introduction

The building industry poses significant impact on environment, social, economic, and health conditions at global level due to one-third energy consumption [1]. The growing population and economy have drastically increased the demand for construction of buildings. In addition, most of the users spend much of their time, approximately 90% in these buildings [2]. Thus, the buildings require comfort level for the occupants, and ultimately entails huge amount of energy, about 30% of total energy demand [3]. Moreover, the building's energy performance is required to operate typical domestic appliances, such as heating, cooling, ventilation, artificial lighting, and mechanical devices etc. for attaining the desired comfort level.

The era of 1960s and 1970s has primitively emerged for green buildings movement. This countercultural movement raised the concerns for the usage of resources, waste, environmental sabotage and intensity of energy uses in building [4]. Several policies and plans have been devised to enhance the sustainability of buildings for curbing the severe impacts of above-mentioned challenges. The development of such buildings paves the way to use energy efficient materials and plays prominent role in energy saving by utilizing renewable energy resources [5], reducing greenhouse gas (GHG) emissions, improving health and comfort levels etc. These buildings are often termed interchangeably as green buildings (GB), high performance buildings, sustainable buildings, and sustainable construction. Confering to the American Society for Testing Materials (ASTM) standards E2114-08, the sustainable buildings are the ones that provide the performance requirements of specified buildings curtailing disturbance and improve the functioning of buildings at local, regional, and global ecosystems. It is considered at both during and after its construction and specified service life [6]. The buildings are neither considered as monolithic school of architecture, nor the practitioners controvert over trade-off between various objective functions. There remains a sufficient unique collection of predominant values, ideas and practices that are determined with socio-technical niche [7].

The buildings pose great impact on society and economy and is considered as the major sector in producing monetary values [8]. The buildings emit huge amount of carbon dioxide and consumes most of the energy in the United Kingdom out of many sectors of the economy as reported by the European Information service commission, 2012. About 26% of waste is being contributed by the building construction, besides emitting greenhouse gases which are detrimental to environmental impacts [9]. Therefore, the sustainable measures have to be devised to establish the construction industry and building sector to gain momentum for green buildings [10].

The Fig. 1 shows that there should be a balance between environment, orientation or ventilation and energy use within the green building. Green Building should focus on the cycle of use and reuse of the resources within its system boundary. With global

Fig. 1 Green building rating concept.

reference, it has been defined that there are various indicators used for the green building. However, through intensive analysis, it is concluded that these three parameters are the main indicators for sustainability assessment of green buildings.

The environmental performance of the buildings is assessed based on the GB assessment methods. These are referred as an instrument to assess and evaluate that the building is green and efficient which is to be ranked accordingly [11]. The environmental performance of the buildings is to be enhanced with assessment techniques that may go beyond measuring energy use in buildings. The GB tool serves as guideline or management tool to address environmental apprehensions over the scheme, design, development and construction and operation of the buildings [12]. These assessment tools provide an opportunity for appraising environmental concerns to stakeholders, promoting sustainable practices, besides playing crucial role for their effectiveness.

Environmental Assessment

The environmental assessment is a process which ensures the estimation and evaluation of short-term and long-term effects of buildings in the surrounding environment. The assessment also involves identifying the ways and means to alleviate, mitigate and eliminate the adverse environmental impacts and or compensate otherwise. The study is required prior to the project to establish all positive and negative environmental impacts constituting technical, economic and social outcomes. The environmental assessment undertakes the following:

- (1) Potential of adverse environmental effects from buildings.
- (2) Measures to mitigate, eliminate or compensate adverse effects.
- (3) Predicts after the measures have been implemented.
- (4) Designs a follow-up program for effective mitigation measures.

It is significant to emphasize the environmental audits that can evaluate the regulatory compliances and management of building operations, which may not be used to identify the nature and extent of contaminants.

The purpose of an environmental assessment is to incorporate design, maintenance, operation and demolition with eco-friendly planning and decision making of green buildings. This would advocate the analysis at each stage for mitigation measures and address adverse effects. The mitigation measures for planning the building environmental assessment may result in various benefits that includes minimizing adverse environmental effects, human health, project cost and delays, risk of environmental disasters, increased awareness for harmonization, probability of transboundary environmental challenges along with contribution for development of natural resources [13].

The environmental assessment framework for buildings have been devised in Fig. 2. The building tools are developed and designed to assist the environmental assessment measures and rate the environment friendliness. These tools are available in different countries and regions that vary from each other due to their databases, users, life cycle assessment, certification and quality. Besides, different types of buildings can be assessed such as, residential (single family and multi-unit), commercial, office, industry, institutional, and hospitals etc. [14,15]. Moreover, it can also be classified as new buildings, existing or under renovation. This criterion categorizes the environmental assessment based on different standards, benchmarks and indicators. The qualitative and quantitative criteria and indicators vary with different tools available, which can be scaled from the

Fig. 2 Framework design for environmental assessment of buildings.

buildings assessment to urbanization and its development. Furthermore, the standardization plays vital role in categorizing all the available tools for environmental assessment. These standards set the norms and regulations for attaining the framework of indicators. These various tools are neither integrated nor adaptive to the changing dynamics for social transformation of buildings. This poses a future challenge, since the later the environmental assessment in the design process, fewer the options would influence the design.

Assessment Methods

The environmental assessment methods in buildings are powerful and effective means for the improvement of performance during its life cycle [16]. Over the past decade, various types and number of assessment tools have been emerged. There are approximately forty (40) assessment tools that have been identified worldwide. Different tools belong to different country and region as shown in Table 1.

The Building Research Establishment's Environmental Assessment Method (BREEAM) among the GB assessment tools is the first and leading method developed in 1990 in United Kingdom (UK). In 1998, Leadership in Energy and Environmental Design (LEED) has been established in the United States. LEED has been widely recognized and dominant building assessment method worldwide and implemented in more than 41 countries [17]. Other popular assessment tools have been listed in the Table 1. Some of these tools are accepted and recognized, however, new assessment dimensions are still significant for countries depending on

their local environmental conditions and types of buildings. The assessment tools may also be unable to reflect building sustainability, refinement and evolution objectively or accurately [18]. The incorporation of cutting-edge technologies, conventions and proficiencies in practice would be refined and evolved with time.

Despite of this situation, there are various possible techniques to establish latest and up-to-date assessment process to enhance existing tools with their strengths and weaknesses. These transformations could be based on statistical database formed with green building practices [19], feedback of GB professionals [20,21], equate the assessment techniques with popular ones and human behavioral and climatic change indicators. Besides all, the approach of equating and analyzing is generally used to drive convenient, accessible and reliable intuitions of green building within the least time [22].

Green Economy in Buildings

The concern over the environmental assessment of green buildings depends on the economic and social development. The integrated development of society, economy and protection of environment has evolved the term green economy [23]. The green economy can be defined as, efficient resource utilization, least carbon emissions, and socially inclusive which drives through public and private investments to enhance income and employment. It also deals to reduce environmental emissions and pollutions, and enhance energy resources efficiency along with the prevention of biodiversity and ecosystem services loss [24]. Thus, creation of green economy is not only promoting environmental protection but also establishing closed-loop ecological alternatives in building sector that can contribute to detoxification and dematerialization of the economy.

The notion of green economy development has been trending since it transforms ecological modernization, environmental improvements and economic development. Developing green economy can also be viewed as to tackle global temperature rise, climatic variations and rise of sea level. Whereas, in narrow concepts, green economy can be understood as low carbon economy that aims to diminish carbon emissions as a part to stabilize carbon index levels [25]. Furthermore, enhanced performance of energy, water and other resources can contribute in green economy that can also raise the building asset value for resale and rental markets. These benefits may act as hedge against climatic, regulatory and environmental risks and make less reliance on inputs with volatile prices that reduces the firms risk exposure.

Sustainability of Assessment Methods

The building project can be considered sustainable if economic, environmental, social and cultural dimensions have been dealt with. The sustainability assessment methods of buildings consider optimization of site potential, regional and cultural identity perpetuation, water resource conservation and reuse, environmental friendly products and materials, maintain optimal indoor climatic conditions, health and safety practices, optimal operation and maintenance and renewable energies supply etc. [26,27]. The sustainability assessment should ensure the practitioners, engineers, scientists and stakeholders for judgement during the building construction, design, use and demolishing of buildings. In such a scenario, a multi-criteria decision method could possibly be devised in decision making for energy efficient and sustainable solution [26]. The building profiles or scores sustainability is dependent on indicators, process results in which the pertinent phenomena are recognized, analyzed and valued.

The sustainability assessment methods are effective and compelling for the enhanced performance of the buildings [16]. The existing and new buildings sustainability benchmarks are assessed differently and each assessment tool may have the capability to rate the building. Although, the accurate and objective reflection of these assessment tools may not be sustainable always, the development, refinement and evolving of the assessment item is therefore the need of an hour [18]. Since, most of the aforementioned assessment tools incorporate new and artificial technologies, principles, regulations and expertise in practice. There would be several ways to develop and evolve sustainability assessment methods, which are to analyze through: (a) Statistical data obtained through green building practices [19]; (b) professionals feedback and experience; (c) comparing the widely used and most recognized assessment methods.

The sustainable environmental issues share common concerns that includes reduction in the use of non-renewable materials, water, emissions, wastes and pollutants reductions. The building sustainability assessment policies may affect the entire life cycle from planning, design, construction to the operations in buildings. The green building and sustainability policies seem to be instrumental in analyzing the challenges, like market failure, information asymmetries, economic externalities. The policy of assessment methods for green building considers the entire life of the assessed building from its planning, design and construction to its operation and demolition. These methods and policies seem to be an influential in analyzing the problems, like market failures, information asymmetries and economic externalities. In order to develop any type of sustainability policy, the identification of challenges which may threat to the development of green building, is very essential. These challenges involve lack of understanding, updated knowledge and awareness, funding, insufficient incentives, uncertainty and risks. The process-related barriers involve lack of measurable requirements, team coordination and collaboration. However, the organizational and personal challenges include commitments from building administration, cooperation between public and government, and incentives availability. The approach to counter these challenges is to propose a uniform policy throughout the world, which is implemented through government to encourage green buildings [28].

Conclusion

The building sector has received much consideration over a couple of decade from engineers, environmental economists, scientists and policy makers that tend to accentuate the resource efficiency within the buildings and reduce its impact on human health and environment. This article has made an effort to encapsulate the theoretical motivation for environmental and economic assessment impacts of buildings. Since, the building industry is considered as one of the main sectors in generating economic value addition and poses a huge impact on the environment, economy and society. An environmental assessment incorporates design, maintenance, operation and demolition with eco-friendly planning and decision making for buildings to be green. These assessments would impose low carbon emission, efficient resource utilization, prevent loss of biodiversity, inhibit ecosystem services and socially inclusive where the growth in income and employment can be driven with public and private investments.

Green Buildings: Risk Factors and Mitigation Measures/Emerging Urban Green Spaces in Dhaka: Planning and Analysis

Introduction

A city is built of public and private spaces. But it's the public space which envelopes with uniqueness and presents a statement of the city (Lopes and Camanho, 2012). Generally speaking, public space includes – “All those parts of the built and natural environment where the public have free access. It encompasses: all the streets, squares and other rights of way, whether predominantly in residential, commercial or community/civic uses; the open spaces and parks; and the ‘public/private’ spaces where public access is unrestricted (at least during daylight hours)” The public space includes the Urban green spaces like- parks, recreational spaces, graveyards, and open spaces. Dhaka, the capital city of Bangladesh, is in acute shortage of public spaces or urban green spaces. The city has been expanding to the north since the Mughal period, but it has a limited scope to create new green spaces in the existing context.

United Nations (UN) stated in ‘Concise Report on the World Population Situation in (2014)’, Dhaka is the eleventh most populous megacity in the world with 17 million people. The increasing population has put an immense pressure to the urban settlement of Dhaka and the green spaces are engulfed day by day to meet the urban sprawl (Nilufar, 1999). So this paper aims to point out the potential lands that can be converted into urban green spaces for the wellbeing of the city and make it a livable and sustainable city for the future.

A minimum of 25% open space (plantation and water body combined) of a city, is required to endure a sustainable environment, declared by United Nations Environment Programme (UNEP). In Dhaka, open space area is only about 14.5% (Byomkesh *et al.*, 2012). In another study by Nilufar (1999), shows that, the total amount of open space in Dhaka include- roads, footpaths, parks, playgrounds tracts, lakes, ponds etc. which is about 17%–18% of city area. According to Nilufar (1999), the total land of Dhaka City Corporation (DCC) area and its population ratio, is only 0.12 acres per thousand of population. In the ‘Draft Dhaka Structure Plan Report 2016–2035’, it is mentioned that 0.07 acre/1000 population is the current ratio of recreational areas in Dhaka. With fewer parks and open spaces, the city is facing gradual encroachment of the open spaces both by private and public bodies. Fig. 1 shows, how in 28 years the majority of urban lands, that were previously agricultural land, vegetation, water bodies or low-lying areas were converted due to the increasing demand for urban land. This process put an immense pressure on natural resources in Greater Dhaka (Dewan and Yamaguchi, 2009). These unplanned land use changes has an adverse effect on the present lifestyle and the flooding events, unbearable air pollution, flash flood, water pollution, loss of biodiversity etc. are taking places as a result.

The study conducted by Nilufar (1999), identifies that the precious open spaces of Dhaka are highly used and there also remains a great demand of more open spaces in our urban life. In spite of growing densification of built-up areas in newer parts of Dhaka, a number of medium and large scale open spaces are scattered in the city. The stock of public open spaces under DCC (previously Dhaka City Corporation) control is approximately 190 acres and under Public Work Department (PWD) is 302 acres. These two authorities cover 0.768 sq. miles of area, which is only 1.4% of Dhaka's land.

The southern part, the older part of the city offers more large public spaces which is more culturally active and historically significant, like – Ramna Park (established during British period in 1908), Sohrawardy Uddayan in 1972 (as Habib (2010) stated, Sohrawardy Uddyan was a Mughal Garden until 1825 and later it was turned into a race course under British Rule), Osmani Uddyan, Dhaka university open areas, Shahid Minar, Majar of Three Leaders (beside Sohrawardi Uddayan), Dhanmondi lakes - Nilufar (1999) estimates the plausibility of their diminished value due to over utilization and rapid urban growth. Unless they can be replicated these valuable assets will permanently be impoverished. But the northern part of the city has South Plaza of National Assembly Building, (which is restricted of public entrance) and Chandrima Uddayan are only large scale urban green spaces available for public gathering. Fig. 2 illustrates the existing open spaces of the Dhaka city.

This research aims to identify the potential lands which exist in use as parks, liner green space like lake brims, but absence of landscape quality, inadequate accessibility and vacant/preserved lands which are under different authorities other than Public Works Department (PWD) and Rajuk, can increase the livability of the city.

The aim of this paper is (1) to locate the potential vacant lands or under-utilized Government lands to be converted into urban green spaces. (2) To identify the criteria or attributes necessary to select an urban green space in city scale and (3) to review the current standard of recreational space ratio to population of Dhaka city and analyze the increased ratio due to the selected land. In achieving the objectives, it is necessary to determine which undeveloped/vacant land and under-utilized government land within Northern Dhaka can be converted fully into or at partially to urban green space respectively. It is imperative to identify the criteria or attributes to select an urban green space in city scale. The question to be addressed in this respect is what are the current standard of recreational space ratio to population of Dhaka city and how the newly selected land through LSA (Land Use Analysis) will help improve this ratio.

Fig. 1 Major land use conversion of Dhaka, (a) 1975–1992 (b) 1992–2003. Reproduced from Credit line: Dewan, A., Yamaguchi, Y., 2009. Land use and land cover change in Greater Dhaka, Bangladesh: Using remote sensing to promote sustainable urbanization. *Applied Geography*, 398. doi:10.1016/j.apgeog.2008.12.005.

Green Space

Urban green space: This is defined as land that consists predominantly of unsealed, permeable, 'soft' surfaces such as soil, grass, shrubs and trees. These green spaces may also include other facilities and hard surfaced areas. For instance – All areas of parks, play areas and other green spaces specifically intended for recreational use, as well as other green spaces with other origins (Dunnett *et al.*, 2002). In this paper it is aimed to follow the definition of *urban green space* (Table 1).

The following table discusses the typology of urban green spaces of UK that will help to determine the type of urban green space to be selected-

Open space: The terms *green space* and *open space* are often used as synonyms. According to Dunnett *et al.* (2002), the external environments between buildings are composed of two distinct spaces: Grey space and green space. Grey space is land that comprises of primarily impermeable, 'hard' surfaces such as concrete or tarmac. Green space land, whether publicly or privately owned, consists of primarily permeable, 'soft' surfaces such as soil, grass, shrubs, trees and water.

Public open space: Is defined as *open space*, both green spaces and hard 'civic' spaces, to which there is public access, even though the land may not necessarily be in public ownership. In other definitions also includes publicly accessible green space without any formal facilities for recreation provision.

Different Zones

Dhaka, a 400 year old megacity, expanded with the context of history. The morphological changes in the growth of the city can be divided into five stages, which show the gradual evolution of the city from southern river bank to the north. The growth and development of Dhaka can be categorized into six periods (Fig. 3), viz. the pre-Mughal period (1205–1610), the Mughal period

Fig. 2 Major existing open spaces of Dhaka city. Modified from: Habib, K., 2010. The post-colonial public spaces and its cultural diversity: The case of national-cultural representative public spaces of Dhaka. Master thesis, Katholieke Universiteit Leuven, Department of Architecture, Urbanism and Planning (ASRO), Leuven, Belgium.

(1620–1757), the East India Company period (1758–1858), the British colonial period (1858–1947), the Pakistan period (1947–1971), and the Bangladesh period (from 1971 onwards) (Ahmed *et al.*, 2014).

The climate is tropical wet and dry. But due to global warming a lot of changes has occur in the natural cycle of seasons. The monsoon season brings nearly 80% of the annual average rainfall of 1854 millimeters (73 in). Southwest monsoon occurs from June till September during the summer months (Wikipedia, 2015).

The city has a distinct monsoonal season, with an annual average temperature of 25°C (77°F) and monthly means varying between 18°C (64°F) in January and 29°C (84°F) in August.

The Local Government (City Corporation) Amendment Act (2011) divided DCC as Dhaka South City Corporation (DSCC) and Dhaka North City Corporation (DNCC) on 4 December 2011. Because of this amendment, DCC was divided into two parts: DNCC and DSCC (Ahmed *et al.*, 2014, c.f. Ahmed, 2012). This study is based on DNCC and will call it *North of Dhaka* (Fig. 4).

North of Dhaka is situated within Longitude 90°20' to 98°28' and Latitude within 23°44' to 23° 54'. Its total area covers 82.638 sq. kms which consists of five zones including 36 Wards (Dhaka North City Corporation, 2014).

The major zones, the areas, and existing number of parks and playground under DNCC authority are enlisted in the Table 2.

Table 1 Typology of urban green spaces in UK*Urban green space*

1. Amenity green space ● All land which is designed primarily for amenity, both visual amenity and enjoyment for access and recreation. ● It consists mainly of publicly owned land but also includes private land like Domestic gardens.			
Parks and gardens ● Areas of green publically owned ● Variety in landscape and horticulture element ● Facilities included like- buildings, sports, playing area.	Outdoor sports areas ● Accommodate sports; including sports pitches, playing fields, golf courses, and other outdoor activities ● Often occurs within parks, except golf course occurs independently.	Play areas ● Designed specifically for children's play ● Occur separately but also often incorporated within parks.	Incidental green space ● Minimal landscape values ● 'left over' green spaces within housing and other forms of development.
2. Functional green space Green space which has a primary function other than amenity or recreation, although some of these areas may also be publicly accessible and available for people's enjoyment. For instance- Nursery, Burial grounds and Institutional grounds.			
3. Semi-natural green space ● A green space that is made up of semi natural habitat. ● It may have been formed by the natural processes of colonisation and succession on abandoned or disturbed ground or by deliberate creation of new habitat. ● Such as- Wetlands and disturbed grounds.			
4. Linear green space ● Occurs in association with linear features, especially transport routes such as roads, railways and canals, but also rivers and streams. ● These spaces are, however, distinguished by their linear character and are often an important part of strategic green space designations such as green links and green corridors.			
River and canal banks ● Green space occurring along the margins of canals or rivers and forming part of the river or canal corridor.	Transport corridors ● Green space associated with transport, includes: the variety of habitats, associated with railways. ● Along roads, and especially the large areas of grassland, scrub, trees ● And woodland found along major roads and motorways.

Open Space Provision Standard for Dhaka Metropolitan Development Plan (DMDP) Area

Dhaka Metropolitan Development Plan (DMDP) (2010), Detailed Area Plan (DAP) only suggested standards for parks and play-grounds at only neighbourhood level in Dhaka city. A standard of recreational open spaces within RAJUK area that requires 0.86 acre/1,000 population, thereby 22,360 acre (90.46 sq.km) for 26 million populations which will be 6% of total area is proposed in DMDP. The following [Table 3](#) shows the breakdown of the suggested open spaces criteria and their land cover.

Open Space Provision Standard in Other Countries

The standards approach for parks and open space provision dates back to the early twentieth century. The park reformers sought to establish minimum acceptable park allocations for urban residents. Recreational standards are affected by the cultural background, age, socio-economic status and demographic structure. The following [Table 4](#) discusses the evolved standard of recreational spaces per 1000 residents in the developed countries-

It shows that the required provision for urban recreational spaces in Dhaka city is even bear than minimum in comparison to other developed countries.

Categorization of Existing Green Spaces in North of Dhaka

There are indigenous urban open spaces of Mughal period, still thrives with social activity in Old Dhaka. For instance – *Uthan-mohalla-gali*, are semi- private and public spaces, attributed to rural spatial layout, whereas, [Habib \(2010\)](#) also referred *Bazar and Chouk* (square) as the larger public spaces in Indigenous Dhaka and used for commercial propose as well as a central place for gathering.

Fig. 3 Historical growth of Dhaka, 1600–2015. Modified from: Ahmed, B., Hasan, R., Maniruzzaman, K., 2014. Urban morphological change analysis of Dhaka city, Bangladesh, using space syntax. *International Journal of Geo-Information*, 1412–1444.

The colonial urban open spaces were the cultural landscape for British and local elites. These spaces later on became the post-colonial urban spaces which served during the 1971 liberation war of Bangladesh and incorporated a new symbol to nationalism. Later on as the city developed to the North, more planned pattern of settlement appeared but the provision of urban green spaces were meagre.

The western standard of urban green space is not applicable to Dhaka city, in terms of hierarchy. Based on nature of the land and the type of open space use, Nilufar (1999) categorized urban green spaces in four types. Here, it is aimed to sort urban green spaces in Northern Dhaka, based on the classification of Nilufar (1999).

This paper aims to select the land for 'Urban Green Parks' typology to increase the percentage of the green open space ratio of Dhaka city.

The Table 5 shows 652.75 acre area is dedicated for 3,957,302 people of North of Dhaka city. From the data in the table, the current provision of recreational spaces in the northern part of the city is about 0.16 acres.

DMDP (Dhaka Metropolitan Development Plan) Structure Plan Policies of Open Spaces

Dhaka City Structure Plan, Vol-I, 1995 [1995–2015] depicted vision regarding city's open spaces but unfortunately they could not meet up the proposal (Nilufar, 1999). The proposed policies are, in brief, as follows:

- POLICY SE/10- Augmenting city open space:
The Municipal Planning Authority [MPA] will seek to augment the City's existing stock of major recreational facilities by means of exploiting the resource of vacant and/or under-utilized Government land within the established urban areas.
- POLICY SE/11- Securing future open space:
It is the MPA's intention to identify and secure sites for major recreational use in the DMDP Structure Plan's all the priority new development areas. It is also recommended that necessary land for flood retention ponds may be assessed to combine them with the recreational open spaces.

However, those policies have not been implemented due to unconcerned and unwilling authorities and lack of awareness and coordination among the implementing agencies. DMDP (1995–2015) standardized 0.16 acres as parks/open space per 1000 populations which is equivalent to 4 acres of open space as parks as part of community services for 25,000 populations as specified in Urban Area Plan (1995–2005).

Methodology of Suitability Analysis

The Landuse Suitability Analysis (LSA) was supported by the spatial analysis functions of GIS through steps including: Identification and collection of spatial data, maps, scoring, weighting and, data integration and GIS analysis, and output evaluation. In

Fig. 4 North of Dhaka, DNCC. Modified from: Iqbal, M.J., (n.d.), 2015. Centre for Urban Studies (CUS), Dhaka. Available at: <http://cusdhaka.org/maps/598/attachment/dcc-north-new> (Retrieved 03.06.15).

LSA, determining the suitability scores for each factor is a compulsory step, and in this study they were regulated from 1 to 4 where a higher score indicates an area more suitable for developing urban green open spaces. Once combined, the resulting map provides a visual tool useful in understanding which areas of Dhaka have superior probability to convert into quality green space and which have lower levels of access. Fig. 5 demonstrates the algorithmic flow of all the necessary steps taken.

Limitations

There are very few previous studies available on suitability analysis of urban green spaces of Dhaka city. So, the current study faced difficulties to enrich the analysis of the findings. The base map used in the current study is 2006 GIS map is from Dhaka City Corporation (DCC). Moreover, the changing rate of infrastructure in the study areas is very high. And also the limited time frame and availability of information over internet are to be considered as limitations.

Table 2 Major zones and existing urban open spaces

Zone	Area name	Area (Sq km)	Population	Parks	Playground
Zone-1 (Uttara)	Uttara Model Town, Kuril, Khilkhet, Nikunjo.	11.570	379,777	6	2
Zone-2 (Mirpur-Pallabi)	Mirpur section-12, Mirpur Ceramic, Mirpur section-10, Mirpur section-14, Byshteki, Mirpur section-11, Bawneabad Area, Mirpur section-6 & 7, Pollabi, Mirpur section-2, Rupnagar, Govt. housing Estate, Mirpur section-1, Box Nagar, Zoo and Botanical Garden, Vasantek, Maticata Manik Dey, Barentek.	21.317	1,002,501	— ^a	5
Zone-3 (Gulshan)	Baridhara, Shahjampur, Gulshan, Banani, Mohakhali, Niketan, Badda, East Rampura, Ulon, West Haji Para, Khilgaon B Zone, Purbo Haji Para, Chowdhury Para, Tejgaon I/A, Kunipara, Arzat Para, Rasul bag, Tejgaon, Boro Maghbazar, Eskaton, Neyatola.	18.987	926,769	14	8
Zone-4 (Mirpur-Kazi Para, Gabtoli)	Golartek, Bagbari, Gabtoli Bus Terminal, Gabtoli, Mirpur Colony, Darus Salam, Paikpara, Ahmed Nagar, Monipur, Parer Bagh, Kazipara, Sawrapara, Senpara-parbata, Ibrahimpur, Kafrul.	11.962	836,132	2	4
Zone-5 (Kawranbazar)	Kawranbazar, Tegturipara, Tejkunipara, Razabazar, Monipuripara, Indira Road, Agargaon, Taltola Staff Quarter, Mohammadpur, Shamoli Ring Road, Adabor, Shakertek, Mohammadpur Azam Road, Jakir Hossain Road, Nazrul Islam Road, Lalmatia, Asad Gate, Khilji Road, Babar Road, Iqbal Road, Aurangzeb Road, PC Culture, Basila, Katasur, Mohammadia Housing, Basbari, Jafrabad, Sultanganj, Rayer Bazar, Bibir Bazar, Madhu Bazar	18.802	812,123	13	20
		3,957,302			

^aAll the open spaces are under Housing and Settlement Directorate and less than 5 acre in total.

Criteria of Suitability Analysis

Suitability Analysis is defined as the most appropriate spatial analysis for land uses, identified by land use suitability analysis based on specific requirements, preferences, and predictor of some activity (Malczewski, 2004). Generally a myriad of data set can be used for the land suitability analysis of urban green spaces based on ecological, economic and social demands. Previously discussed in [Table 4](#) which has been adopted from C, the open green space of Dhaka city categories into three basic typologies and “Urban Green Parks” is the major park type. But further liner green areas beside lakes or wetlands have also been enlisted in as semi natural green corridors which may host any large public activity; they also fall into the ‘Urban Green parks’ type of open space. The identified open green spaces are shown in the following [Fig. 6](#).

Table 5 Types of urban green spaces in dhaka

Type of open space	Criteria	Standard area (Acre)	Existing example	Zone	Area (Acre)	Desistance from home
Urban green parks	Large open spaces, may include semi-natural or liner green space that accommodates any activity and large group of user	30–120	Chandrima udyan North and South Plaza of National Assembly Building [including National Graveyard, Officers housing & Lake]	5 5	77 95	1.2–1 km
Urban development open spaces	Urban plazas/parks of various size in commercial and institutional areas which has historic, cultural or political importance	2–8	Mirpur Intellectual's Memorial with Park Shishu Mela Shere Bangla Nogar Park National zoo Botanical Garden Pantha kunja	4 5 5 4 4 5	11.6 1.43 6.16 186 208 0.96	800 m
Urban recreational areas	Open spaces developed and assigned for residential outdoor recreational activities	0.5–9	Uttara Sector 3 Park Uttara Sector 4 Park Uttara Sector 6 Park Uttara Sector 07 Park Uttara Sector 13 Park Gulshan Taltala Park Gulshan Park at Road no 103 Gulshan Ladies Park Gulshan Tank Park Baridhara Park Khilgaon Chowdhury para children's park Dr. Fozle Rabbi Park Play Field of PC Culture, Shamoli Khilji Road Children's Park [PC Culture, Shamoli]	1 1 1 1 1 3 3 3 3 3 3 5 5	3.28 3.2 5.75 11.44 6.16 4.2 7.3 5.7 7.5 2.14 4.97 2.1 2.86	400 m
Functional open spaces	Serves functions other than recreation in residential, commercial, industrial area	Variable	Banani grave yard Mirpur Graveyard Kazipara Graveyard Graveyard in Section 13 and 11. Total area	3,4	Variable 652.75	Wherever feasible

**Fig. 5** Methodological flowchart indicating the land suitability analysis (LSA) for urban green space development in North of Dhaka.

Hence, the potential land and liner green spaces have been included in proposed [Table 6](#) with their existing physical, meta-physical criteria, which are 30–120 acre in size and able to host large public gathering. They are as follows:-

The suitability factors accessibility, Historic-cultural value, flooding and water body are taken into consideration other than size, buffer or distance from locality, existing land use and density.

- **Size:** Size is a prime factor for the urban green space in Northern Dhaka. So that it can accommodate the cultural festivals like Pahela Baishakh (Bengali new year), National events like Independence day, Fairs, Dhaka Art and Architecture Biennale etc. all the part and parcel of Bengali life style. It is also vital for the ecology and to enhance a sustainable city for living.
- **Accessibility:** Using space syntax analysis ([Khan, 2014](#)) showed that the use of parks can be augmented by making their accessibility better i.e., by providing entrances from other adjacent roads of parks in Dhaka city. Ease of access of any system of public space depends on the number of alternative access roads. More favorable are major roads, as they ensure more easy accessibility. A large space like Botanical Garden at Mirpur in Dhaka is underutilized, because the road network does not offer a clear approach.
- **Land Use:** Land use includes how people use and manage the land ([Wikipedia, 2015](#)). The economy is interrelated to land-use. The mixed use offers- commercial, residential, institutional uses existing in a particular area that can bring an array of users from different socio-cultural background. Otherwise a specific area can be comprised of dedicated commercial, residential, institutional, industrial users.

Fig. 6 Proposed lands for urban green space in North of Dhaka.

Table 6 Proposed land criteria

<i>Proposed lands in 5 DNCC zones^a</i>	<i>Area (Acre)</i>	<i>Land use</i>	<i>Buffer of 1.2 km covering maximum DNCC zone (nos)</i>	<i>Accessibility</i>	<i>Historical or cultural value</i>	<i>Flood prone</i>	<i>Water system influence</i>
National Parade Ground zone 4	435	Institutional restricted in nature	4	Bounded by arterial road at west, two major road on south and east, no access from north and eastern corner	Historical site Runway was built during 1942 world war II	Low risk High land	Water body within the site
Hatir jheel lake (INCLUDING WATERBODY) infrastructure Zone 3	302	Mixed use	2	Bounded by major traffic loop	Recreational/tourist spot – Thousands of people gathers at weekends	Low risk New developed	Surrounding a lake or waterbody
Baridhara Lake side Rajuk park Zone 3	41.73	Mixed use	2	Bounded by two major roads at north- south, secondary road at the east and west	Recreational/tourist spot, daily users like joggers	high risk	Surrounding a lake
Uttara Sector Lake Zone 1	29.84	Residential	1	Bounded by two major road at north- south, one secondary road at east and alley on the west	Recreational spot- daily users like joggers	Very high risk With low land	Surrounding a lake
TRADE fare field Zone 5	32.09	Institutional Occasionally used	2	Only accessible from secondary road at north	Culturally active- once a year a trade fair takes place for one month	Low risk With high land	No water feature
Rafiq lake Zone 3	23	Residential	1	Only accessible from few alley of the neighbourhood	Neither culturally nor historically significant	Very High risk with low land	Surrounding a lake
Bangla college Pond Zone 4	23	Mixed use	3	Only accessible from the alley	Historical site Genocide spot during 1971 liberation war	High Risk with low land	Surrounding a lake
Khilkhet Lake Zone 1	20	Mixed use	1	Bounded by major high way at west, and 2ndary road at east	Neither culturally nor historically significant	Moderate risk	Surrounding a lake

^aThe demographic data or density is already mentioned in [Table 2](#), that's why it's not been repeated in the [Table 5](#).

Table 7 Suitability classes and scores

<i>Factor</i>	<i>Suitability class</i>	<i>Class description</i>	<i>Score</i>
Density	High	699,910/sqkm	4
	Moderate	48,828–47,028/sqkm	3
	Low	43,198/sqkm	2
	No	33,024/sq km	1
Accessibility	High	Bounded by four major rd.	4
	Moderate	Bounded by one major rd. two secondary rd.	3
	Low	Bounded by two secondary rd.	2
	No	Bounded by Alley	1
Size	High	≥ 120 acre	4
	Moderate	< 120 but ≥ 40acre	3
	Low	< 40 but ≥ 30 acre	2
	No	30 acre <	1
Existing land use	High	Mixed use	4
	Moderate	Institutional	3
	Low	Commercial	2
	No	Residential	1
Historical or cultural value	High	Historic site	4
	Moderate	Culturally active site	3
	Low	Tourist area	2
	No	Other areas with potential of high historic value	1
Flood prone	High	Low risk	4
	Moderate	Moderate risk	3
	Low	High Risk	2
	No	Very high Risk	1
Water system influence	High	Besides waterbody or lake	4
	Moderate	Water within site	3
	Low	Distance to main reservoir, lake is < 10 m	2
	No	No waterbody within 50 m or vicinity of site	1
Buffer of 1.2 Km radius	High	Covers 4 or all zones	4
	Moderate	Covers 3 zones	3
	Low	Covers 2 zones	2
	No	Cover the only zone it belongs to	1

- *Density*: Population size is an important factor to be considered. Different countries around the world have their own standard of green space ratio per 10,000 people. Even it may vary from city to city within a country, for instance – In US, Boston offers 7.9 acres per 1000 population, whereas New York offers 4.7 acre per 100 ([Harnik et al., 2012](#)). Densely populated Dhaka is unable to meet this bear minimum ratio. In zone 2 and 4 there is a serious lack of large or even neighbourhood scale urban green space, but it has the highest population density among 5 zones. Therefore, it will help to decide which land is more vital.
- *Historical and cultural values*: History and cultural values is another social factor which will include value to the urban green spaces. [Uy and Nakagoshi \(2008\)](#), [Manlun \(2003\)](#) selected this criterion to preserve the site for future generations and by using the space. In the current study, few selected sites have significant historical value – Liberation war genocide field or first establishment of an airport in Dhaka city.
- *Water system influence*: In the densely populated area, it is difficult to find vacant lands, so the existing lakes and lake side have been also included as potential green space. Because Dhanmondi Lake (showed in [Fig. 1](#)) development in Dhaka South city corporation is a successful example of urban space of 15 acre which consist of the soft and hard space excluding waterbody area. And it will also help to terminate encroachment of wetlands caused by urban sprawl and may play a major means of flood and storm water runoff mitigation. In Vietnam, the Hanoi masterplan includes green spaces beside water bodies as valuable landscapes in lieu of strategic planning ([Uy and Nakagoshi, 2008](#)).
- *Flood*: Flood is a form of natural hydro-meteorological phenomenon and very common in Dhaka due to heavy rain, dense settlement and poor drainage network. [Sarker and Sivertun \(2011\)](#) studied various factors of flood and produced a flood prediction mapping of the city, which is used as reference of areas to flood risk.
- *Distance or Buffer*: As it is aimed to propose urban green proto type of “Urban green parks”. Of which accessibility radius of 1.2 km is acceptable. The proximity analysis by [Etingoff \(2014\)](#) determined access to green space outside of the immediate area. In this study, the outer ring of each zone has been buffered to 1.2 km, and then it is identified which land falls in the strategic location to be covered by maximum number of zones.

Table 8 Weighing sub categories (a) Size, (b) landuse, (c) historic cultural values, (d) flood risk, (e) population, (f) population (g) buffer (h) water system influence by applying online AHP calculator

Resulting Priorities				Resulting Priorities				Resulting Priorities			
Category	Priority	Rank		Category	Priority	Rank		Category	Priority	Rank	
1 >150 Acre	45.7%	1		1 Mixed use	51.0%	1		1 Historic site	49.9%	1	
2 120 acre	33.5%	2		2 Institutional	27.1%	2		2 Culturally active	31.3%	2	
3 50 acre	14.5%	3		3 Commercial	15.2%	3		3 tourist area	12.0%	3	
4 30 acre	6.3%	4		4 Residential	6.7%	4		4 other areas	6.8%	4

Data Analysis

The proposed lands have been drawn in polygon in Google Earth 7.1.5 and saved as .kml file. Then this .kml file has been converted into shape files using QGIS Desktop 2.8.2 and projected in ArcGIS 10 by using WGS_1984_UTM_Zone_46N projected co-ordinate system for Bangladesh.

In LSA, determining the suitability scores for each factor is a compulsory step, and in this study they were regulated from 1 to 4 of scale. Here a higher score indicates an area more suitable for developing urban green space. In the Size map, for instance, greater than 120 acre in size spaces receive the score 4 (highest suitability), < 120 but ≥ 40 acre in size score 3 (moderate suitability), < 40 but ≥ 30 acre in size achieves 2 (low suitability) and smaller than 30 acre in size score 1 (no suitability). The following Table 7 describes the suitability classes and scores for every criteria. They are illustrated in map. They have been converted to raster image for the weighed overlay in ArcGIS 10.

Analytical Hierarchical Process is a mathematically multi-criteria decision making process. Pairwise comparison method can exchange subjective measurements of comparative importance into a linear set of weights that is developed by Prof. Saaty (1980) known as Analytical Hierarchical Process (AHP). An online AHP Calculator created by Goepel (2014), has been used to obtain AHP of four degree and pairwise comparison matrix for both factors and sub category and define each criteria's relative importance by weighted score. It precisely influences the result, and is complicated by interacting of factors with each other (Uy and Nakagoshi, 2008).

Table 9 Priorities of Criteria

Resulting Priorities			
Category		Priority	Rank
1	Size	32.1%	1
2	Density	9.5%	4
3	Accessibility	22.9%	2
4	Existing Land Use	8.5%	5
5	Historical or Cultural Value	4.8%	6
6	Water System Influence	17.6%	3
7	Buffer	2.8%	7
8	Flood	1.8%	8

Source: Generated through: Goepel, K. D. (18 May, 2014). BPMSG AHP Online System. Retrieved 20 June.

Consistency ratio (CR) for the above weights have been tried to maintain fewer than 10% and this consistency is acceptable. Because, it is less than 0.10 which means the subjective judgments need not to be revised.

Finally the weight has been normalized and the spatial analysis tool has been used in ArcGIS 10 to overlay the previously rasterized maps to obtain the final composite map.

Results and Discussions

The priority of each Criterion contributes to the priority of the Goal. The priority of each Subcriterion contributes to the priority of its parent; the AHP software (Goepel, 2014) calculated the global priority of each Subcriterion. The Table 8 shows the priority of each sub-criterion. The local priorities throughout the hierarchy will add up to 1.000, like this:

Based on the entered judgments the AHP has derived the priorities for the factors against which each of the eight lands will be compared. The consistency ratio (CR) is 7.4%. They are shown in the Table 9 below.

The next step is to evaluate each of the lands with respect to these factors. These evaluations are done in ArcGIS 10 by normalizing the weights. The spatial analysis tool produces the rasterized images (Fig. 7) which show the suitability of each land with respect to each category. Then these rasterized maps are then overlaid with derived priorities for the factors. Final overlay of all the maps has produced the desired map (Fig. 8) and the most suitable land has been selected for conversion which is the old airport at Tejgaon.

The map in Fig. 8 clearly depicts the most suitable vacant or underutilized land, suitable for converting into new Urban Green Space in North of Dhaka. The current condition of urban green open space is dire and inadequate urban recreational spaces initiated this research. However the selected criteria are unique to the lands but not limited to the scope.

These physical attributes have helped to define the ultimate land which used to be the Old Airport of Dhaka. It has received the highest scores in all criteria except the existing land use criteria. The area is used as Base Bashar by BAF (Bangladesh Air Force) and is a highly restricted area. It covers the densest catchment area, bounded by major road for ease of accessibility, and has the biggest area. It was the first international airport of Bangladesh, so it has historical-cultural value and the site is located on the high plane of Dhaka which is less prone to flood and has water body inside the area. Also the site covers 4 zones of DNCC in 1.2 km radius. By critically fulfilling highest scores in most of the criteria, old airport of Dhaka is certainly suitable for converting into urban green space. The 435 acre of area will also increase the provision of the recreational area per 1000 population in the north of Dhaka city.

The current ratio is only 0.16 acre/1000 population. This is also below the standard of DMDP standard 0.86 acre/1000 population. If Old Airport at Tejgaon can be converted into the green area of the city, which is also proposed in the Draft Dhaka Structure Plan (2016–2035), the ratio will increase to 0.27 acre/1000 population.

Followed in order of importance comes in second- Hatir jheel, which is a lake side corridor and needs landscape planning to overcome its current issues. It has received highest scores in accessibility, size and existing land use. It's a low land and prone to flood, that's why received the lowest score in flood prone criteria. It's also less suitable in terms of buffer and existing landuse.

In third-Rajuk Baridhara Park and Rafiq Lake Khilgaon are suitable to become the urban green space, but these sites received the highest scores only in exiting land use criteria, and are less suitable in terms of size, density, accessibility,

Fig. 7 Suitability scores for (a) density, (b) accessibility, (c) size, (d) existing land use, (e) historical and cultural value, (f) flood prone (g) water system influence (h) buffer.

SUITABILITY ANALYSIS OF PROPOSED URBAN GREEN SPACES IN NORTH OF DHAKA

Fig. 8 Generated Composite map of proposed lands with highest suitability.

historical-cultural value, buffer and flood prone criteria. But these lands can be protected and converted into community scale green spaces.

In fourth place come- Bangla college pond and Khilkhet Lake, in fifth- Uttara Lake Park and in the last- trade fare field. The trade fare field shows no suitability at all for future development of urban green space. To enhance Trade fair field's viability it can become an extended part of Chandrima Udyan to increase the provision for recreational area.

Conclusion

The research has led to identify the most appropriate vacant land of North of Dhaka which will serve to all most all zones, except zone 1. In terms of landscape architecture, the Old Airport can contribute to increase the green space ratio from 0.016 to 0.27 per acre after the development of the site. Diverse flora and fauna habitat can be introduced in the heart of the city. In identifying the desired land physical and meta physical attributes were identified that helped to select plot. The establishment of an urban green space in the congested area of North dhaka will not only increase the land value in terms of aesthetics and landscape but it will also help to take steps to build sustainable city." Policy se/10- augmenting city open space" of Dhaka Metropolitan Development plan (DMDP) structure plan can be implemented to take over the viable land.

It will also help to develop economy and new users. The habitants of North dhaka will not have to travel down to south for any urban gathering if this land is established as an urban green space at the heart of the city.

But further research is necessary for better understanding and social criteria like users should be included for more accurate outcome of results. For more intense results, if funding are available, more land should be identified to develop community parks and greenbelts surrounding the city. Previously Nilufar (1999) suggested to convert the Old Airport into urban green spaces and resemble it's potential with the Central Park of New York. This heuristic research will certainly create a new horizon in the field of landscape architecture in Bangladesh. To develop a more sustainable city we must understand the growing needs and pressing problems of the current lands. Multi criteria sutability analysis is surely an important tool, only used by the planners in Bangladesh. But it's the first time it has been used to identify lands for landscape planning purpose.

Introduction

In this modern era of the 21st century, the need of energy as fuel has been increased from two decades. Human life has become only dependent on energy carrying resources. Without energy, the life seems dull and colorless (Kumaravel and Abdel-Wahab, 2018). From the chores of a peasant to the patients in the hospitals, from transport to vehicles to aircraft purposes, from cooking to meals to pressing dresses, even from conversion of energy from one form to another including mechanical, chemical, electrical, solar, cell, etc., the energy sources are required. This energy is obtaining from the sun, earth, water, air, waste products of animals and dead plants. Greater than 70%–80% of energy is utilized by the non-renewable resources like fuel, oil, coal and in the form of natural gas. But, renewable energy sources like solar (Vanderhulst *et al.*, 1990), wind (Kempton and Tomić, 2005), geo-thermal (Banerjee *et al.*, 2015), biomass (Sriram and Shahidehpour, 2005), tidal (Twidell and Weir, 2015) and hydro power (Akhtar *et al.*, 2018) are used to produce only 15%–20% energy carrying devices utilizing for human objectives. If we take command over the production of energy releasing from the sea water (Ferreira and Estefen, 2011), that is, abundance in quantity all over the earth, then, the need of energy may be minimized, so that development rate can also be increased. Therefore, to quench the thirst for production of energy is now under considerable view at a large scale. To discuss these energy resources, we perform a comparison between the basic energy resources is given in this article. To meet favorable methods to overcome the restricted aspects that are becoming the hurdles among the existing methods, different modern technologies have identified (Ellabban *et al.*, 2014). The difference in the renewable and non-renewable energy resources is also described in this review. These energy carriers are useful in the form of light and heat in the building, offices, hospitals, schools, public stations, at work-shops, ware houses, hotels, libraries at shopping malls and market centers as well agricultural and industrial field of life is equally important. All these energy carriers including domestic, commercial, industrial and agricultural objectives are obtained from the sustainable as well as non-sustainable energy resources. It is also seen that the renewable energy resources are in abundance and natural occurring without any cost. Out of all over world research on the energy, there are 20% sources for Bio-chemical, 21% for microbial desalination, 10% for photocatalysis, 12% for seawater batteries, 9% for petrochemical industries, 4% for electro dialysis and 24% for others. As with the increasing population, energy has become the primary block for diversity in every walk of life. Since, all the set-up round the world depends upon the energy. The energy utilization is taken as the backbone for its progress. Out of all the energy usages there are 40% sources used it for industries, 24% for globalization consumption, 30% for domestic chores and commercial objectives and remaining part is used for other applications including agricultural.

In developing and under-developed countries, there exists opponency between energy usage appliances. Since, there are 2 billion citizens in developed countries. There is deficiency in achieving the suitable amount of power suppliers. Above three million people's lives in the under-developed countries depend upon the wood, kerosene, coal, charcoal and dung for their domestic purposes. Contrary to it, urbanized locations accounted for seventy percent (70%) of energy consumption at commercial scale. Pakistan, with 13% of the world's population used only 2% of world energy. If American society uses the 100 units for conveyance and only 1.5 units are used by Pakistanis. Pakistan as an agricultural country, majority peoples used dry wood, livestock wastage and agricultural wastes for their heating and cooking purposes. The minority of the peoples who lives in urban areas are facilitated with industries, free transport, technology availability and home appliances. This energy is obtained from renewable as well as non-renewable sources. The energy share in each walk of life is the result of commercial resources as petroleum, coal, charcoal, sun energy, etc.

Main Energy Resources

Among the efficient energy resources, solar and sea water can play significant role to numerous energy harvesting applications. The energy produced by them is used in the industries at commercial as well as at agricultural level. Solar energy; with each day of the rising sun, provide us heat and light. This solar energy when reaches the earth in the form of light and heat, some fraction of its energy is reflected back to the space and some fraction is absorbed through plants by the process of photosynthesis. These are divided in two categories as;

- (1) Renewable energy resources and
- (2) Non-renewable energy resources

Renewable Energy Resources

Renewable energy resources are biomass energy resources available in the naturally in abundance and exist everywhere around the world. These sources are unlimited, i.e., they can be recycled for many times to obtain the energy. They consist of dry fuel wood in

forests, Petro-plants and trees, biomass base plants, livestock dung, solar energy, wind power, water energy, and geothermal energy. These energy resources can be recycled under viewing and taking some suitable steps in nature. Renewable energy sources produce eco-friendly and pollution free environment. These energy resources are widely using in all over the world. The advanced countries are using the sun light and wind with hydra power to produce heat and warmly environment. In Pakistan, a place called Sui; there is a big power plant for natural gas where sulfur di-oxide and other odor gases are treated to generate the smelt gas. Consequently, the gas leakage can be realized and can be safe from a serious accident. The solar energy in solar panel has become a forceful mean to day at every place round the world. The solar plate absorbs the ultraviolet rays from the sun and converts it to electricity by using in home appliances. There is not too much cost consumption for the purposes of wind producing setup than other sources producing energy. The wind energy rotates the turbine and thus the generator produced electricity through wind-mills. And further by the transformer it is facilitated to domestic areas by grid stations and used. Geothermal energy, another renewable energy source, used to produce energy in the form of fuel and electricity. Natural heat from the earth core is used to turn the turbines planted in remote areas, resulting in the production of energy as heat and electricity. However, a small amount of geo thermal energy is used and consequently a huge amount of electricity, about 10,000 times more energy is generated.

Water, a natural gift, has enough pressure to create the energy of several Giga voltages. The small amount of kinetic energy of river water is utilized, and as a result, the energy about the amount of country requirements can be achieved. The dams all over the world are using the same principle and producing the energy as heat as well as electricity, a biggest need for energy requirements, and removing the thirst for energy. The energy producing by the hydra power is at the higher level all around the world. Now a day, it has become the biggest source of electricity. Biofuel is conversion of biomass, including the livestock wastage with plants and the animal's fossils are treated to combustion under the high heat that convert the waste products to steam and this steam is used to rotate the coil and produce electricity.

In the developing countries, the biomass-based energy generation methods are efficiently used due to its versatile properties. The biomass based waste-materials have to be crushed through machine and then to be processed by grinding to form the required fine form of material. This material is then ionized under pressure to turn it into heat and consequently this heat is used to generate electricity by the turbine (Boyle, 2004). Thus, the electricity is produced in remote areas. In this way, fuel crisis, energy crisis, water purification problems have been overcome up to 70%. In the future, if the energy necessities would be control over if the struggle will continue. However, these methods are producing a high amount of energy and are utilizing energy in the world, but there are some drawbacks of them. However, they are eco-friendly, but they are polluted to some extent as well. Due to un-advancement in some countries, the availability of the material is uncertain for many countries. Even the advanced countries are also facing these adverse defects (Johansson *et al.*, 1993). The death rate of the world population has been increased up to 30% due to polluted environment. Among 5 men of the world each three men had fallen prey into serious disease.

Non-Renewable Energy Resources

Non-renewable energy resources that are produced for long a time and are accessible in controlled amount. Due to control utilization, they are fatigued for a limited time. Non-renewable energy resources are petroleum based, coal, natural gas, nuclear energy fossil fuels, etc. These sources are obtained by the cracking and reforming of by-products.

Nuclear energy is obtained by the nuclear fission reaction of uranium and thorium. In this reaction, the neutron with its sufficient energy strikes to the uranium atoms and, as a result, and adduct of the reactant with the catalyst is obtained for a short period of time, this adduct is unstable and get stability by the emission of krypton and barium with extra three neutrons and an amount of energy of mega voltage range is obtained. If the neutrons are controlled then the reaction is controlled, but, if the neutrons are not captured, they further react with other uranium atom to do a reaction and thus continued the reaction as shown in Eq. (1).

As a result, the fission chain reaction takes place. That is a function of the atom bomb. Fossil fuels; dead plants and animals are buried under the ground for a long period of time. Due to global warming and increasing temperature and pressure on earth, these decay objects are converted into fuel. This fuel contains coal, petroleum including carbon. These compounds are organic compounds found also in proteins, carbohydrates, enzymes, lipids, vitamins and nucleic acids. Energy is obtained by the petroleum, coal and natural gas reservoir contains organic compounds. The dead plants and animals, due to bacterial and chemical reactions are converted into peat resulting into the coal under high temperature and pressure.

These sources have shorter duration to sustain themselves. Fractional energy achieved by petroleum is given by the following Table 1:

These gasoline products are found from the biomass material with the help of some renewable energy resources. Non-renewable energy sources are the carriers of polluted environment and the poisoned air. These energy carriers are the greatest source of disease, causing death (Han *et al.*, 2015). Thus, the death rate has been increased from last decades. The polluted air has created a number of patients suffering from asthma, serious flue, chest attack diseases and many other diseases.

Table 1 The table shows the fractional volume of non-renewable energy resources

<i>Fraction</i>	<i>Boiling point range (°C)</i>	<i>Uses</i>
Natural gas	<20	Fuel, petrochemicals
Petroleum ether	20–60	Solvent
Gasoline	40–220	Motor fuel
Kerosene	175–325	Heating fuel
Gas oil	> 275	Diesel and heating fuel
Lubricating oil	Viscous	Lubricants
Asphalt	Solids	Paving and fuel reducing

Sea Water Abundancy

Sea-water found on the earth is in abundance and is about 90% in nature. This sea-water contains NaCl, MgCl₂, MgSO₄, CaSO₄, k₂SO₄, Ca₂CO₃, and some MgBr₂. In order to meet the progress in each field of life, the production of energy as a fuel has now become basic requirements throughout the world. Since, the temperature at near the earth surface is about high of 26°C. A current is, like a vast river in the ocean, transferring fluid from one place to another. The differences in temperature, wind and salinity cause current. These currents are responsible for the movement of water in the ocean and sea. Moreover, the earth water is also found in the form of salinity at greater amount. Due to such a marvelous amount of water there is a need to produce electricity at such higher level. Suitable steps are followed by various companies to promote their countries and states.

Hydro-Electric Power

Sea power is another superb source of the renewable energy as a fuel for the human being's benefits (Ferreira and Estefen, 2011). The energy released by the sea water can be converted into the electric power by turbines. This electrical or mechanical energy can also be used as water purification for home appliances and other commercial chores. The solution was separated and air was passed through alloy, water reactor and fuel cell. The whole mixture was then reacted with water and converted it into hydrogen by catalysis process. Owing the efficient hydroelectric energy, the world's maximum energy shortage has been sustained (Estefen *et al.*, 2007). The other method that can play significant role to generate electricity through hydraulic energy conversion is ocean energy converters (OEC). It converts the seawater into electricity which then converts it into mechanical energy. The energy generated through these sources was found to be effective for domestic, industrial as well as agricultural requirements.

Wave Energy Converter

According to Brooke (2003) and (Liu *et al.*, 2014), wave energy converter (WEC) is managed by remote areas of the seashore, the coastline and offshore devices. This process is based on the ultra-pressurized chamber that has the ability to store the wave energy though the fast movement of water. The pressurized water is then accumulated into low-vacuum and ultra-high vacuum system. The water is stored in hyperbaric chamber and ultrahigh pressurized pneumatic chamber. These chambers worked as a hydraulic press. When the pressure of the press has reached at its critical operational value, the water is driven through the valve which is directly connected to a generator that rotates the turbine and as a result, electricity is produced. The power obtained by ocean is converted into electrical/mechanical energy. This kind of energy is then treated through desalination of water. Consequently, obtained water is used for cooking, drinking and many domestic tasks, industries suppliers and agricultural cultivation.

Hydro Power

Water is the most conventional renewable means of energy. Energy is obtained when water flows or falls off from a height. Hilly and highland areas like mountains and springs are suitable for this objective, where water flows in large continuous sequence falling from slopes. Dams and power plants are built over rivers. Falling rain water with river water is stacked in dams to fall from heights. This stored water flows out through pipes in specific directions inside the dam, which drives turbine blades placed at the bottom of the dam. Thus, the speedy rotating blades then turn the generator to produce electricity. This energy is called hydro-electricity. The water is used in crops and fields for irrigation after the generation of electricity.

Pressure Retarded Osmosis (PRO)

The pressure between the river and sea water at the height is used to change the SGE (salinity level) to mechanical/electrical energy. Water flows with the chemical potential from river water with low pressure to the higher level in the seawater. The mechanical power is utilized to expand the volume level in the higher concentration region. This pressurized water is used to turn the turbine

Table 2 The PRO result for energy generation with natural and commercial sea salty water in draw solution form

Membrane	HC	LC	Pressure	Power density (W/m)	References
SiO ₂ /polyacrylonitrile	Seawater brine	80 mM NaCl	15.2	15.2	(Song <i>et al.</i> , 2013)
Hollow fiber membrane	Seawater brine (1000 mM NaCl)	10 mM NaCl	20	7.0	(Zhang and Chung, 2016)
Thin film composite-polyethersulfone	Sea water brine	Wastewater concentration	20	4.6	(Wan and Chung, 2015)
Thin film composite-polyethersulfone	Sea water brine	Deionized water	20	21.7	(Wan and Chung, 2015)

resulting in the generation of electricity. In the chemical format, higher and lower concentrations are used to draw and feed solid solutions. **Table 2** shows the PRO result for energy generation with natural and commercial sea salty water in draw solution form.

The experimental results revealed that the energy production is strongly affected by using membrane characteristics and quantity of LC/HC (light chains (LC)/heavy chains (HC)), that is, feed and drawn solutions. Further, membrane efficiency is also influenced by reverse solution permeation instead of forward solute permeation. At the same time, the inside concentration polarization and outside concentration polarization was found to be 95% and 96%, respectively. The treated wastewater, being a feed solution, has also become an attractive choice for energy production using PRO. Pretreatment of wastewater by ultrafiltration and nano-filtration are getting higher efficiency and more advantageous when compared to other conventional techniques.

Electricity From Biomass

Biomass is the organic material generated by dead plants and animals waste that are buried underground for a long period of time. After many years due to global warming and high temperature of the earth these waste materials are converted into the organic products like oil, petroleum, coal etc. These materials that are combustible are also called biomass. Biomass having organic compounds comprises of carbon, hydrogen, and oxygen. Biomass with plant and animal's excreta are used as fuel energy and for nourishing and growth of plants and seeds (Liu *et al.*, 2013). There are some important kinds of biomass such as: wood, livestock waste, bagasse, human waste, etc. However, coal is the main part of biomass containing hydrocarbon. In spite of this, it contains the waste product but it is considered more efficient source of energy throughout the world. There are many applications in the society in which biomass are used. It is considered more important than other energy source. Biomass can be oxygenated to produce heat and electricity and because of this, it is widely used in combined heat and power plants (CHP). It also can be used in combined state with fossil fuels to improve the characteristics of combusted residues. Biomass can replace the petroleum as fuel. Biomass with fossil fuels can also be used to generate electricity.

Organic waste products in the form of hydrocarbons such as dead plant and animal products, animal dung and food waste are converted into gaseous fuel called biogas. This organic waste is decomposed by bacterial microorganisms in biogas tankers to emit biogas which contains mixture of methane CH₄ and carbon dioxide CO₂ gases. Biogas is a conducting fuel for cooking and lighting houses and building and produces huge amount of organic manure annually. Energy is everywhere in nature, but the harnessing of this energy is difficult as well as costly. Each one of us can make a competitive arrangement by not wasting energy.

Methods of Extracting Energy From Biomass

Thermal energy, liquid, solid and gaseous fuels with other chemical products can be extracted from biomass by any processes. In the United States, the bio energy also called bio power is used for the energy generation in the form of electricity at the rate of 10 GW capacities. But now a days, majority of technical sources focus on the direct-combustion based technologies. The future performance will be better by co-firing the biomass with coal and invention of new methods like gasification, the combined system of heat and fuel, fuel cell arrangements and modulated systems. The basic bio-power technologies are based on the process of direct combustion, alcoholic fermentation, anaerobic digestion, pyrolysis and gasification. Specific sources of energy are given in **Table 3** as follows:

Direct Combustion

It is the simplest method for energy evolution from biomass. The industrial oxygenated availabilities can combust many ionized biomass products like biomass fuel, wood, crops residues, wood pulping, municipal wastage and livestock wastage as animal dung. The biofuel is burned to generate steam and the steam at high pressure rotates the turbine. As a result, the turbine rotates the generator and electricity is produced.

Gasification

Gasification is another process for the generation of energy from biomass in which, a solid fuel is combusted at high temperature and insufficient oxygen to generate gaseous fuel. It contains the mixture of gases, including carbon monoxide (CO),

Table 3 Specific sources of energy

<i>Field and plantation biomass</i>	<i>Industrial biomass</i>	<i>Forest biomass</i>	<i>Urban waste biomass</i>	<i>Aquatic biomass</i>
Agriculture crops residues: Cobs, stalks, straw, cane etc.	Agro-industrial processes: Husk, whey hides and skin waste.	Timber.	Municipal solid wastes.	Microalgae blooms.
Edible matters from crops: Pulses, fruits nuts, spices, lint	Oil cakes, Sugar molasses, Sugar bagasse.	Log residues forest floor debris.	Sewage sludge.	Sea weeds.
Dedicated energy crops: Bamboo, willow, poplar etc.	Fruit and pulp debris saw dust.	Animals carcass	Kitchen and canteen wastes.	Fresh water weeds.
Plantation debris: Leaves, barks, trunks, etc.	Shavings, Fermented, Microbial mass.			Dead fishes.
Livestock wastes: From fields, slaughter houses.				

carbon dioxide (CO₂), nitrogen (N₂), hydrogen (H), and methane (CH₄). The gas is used to drive the turbine and electricity is produced. This process has many advantages than combusted solid fuels. One of them is used for the convenience and other is used for resultant. Methane can be used as natural gas for burning purposes. Another advantage for the gasification process is to burn many polluted impurities and becomes a source for some removal of pollution free particles (Kubacka *et al.*, 2012). Under some specific conditions, it can also be used to produce the hydrocarbons by mixing of carbon monoxide and hydrogen and can be replaced by fossil fuels. Hydrogen is also a fueling agent used to produce methanol and ethanol.

Pyrolysis

The simplest method, the pyrolysis method, includes heating the biomass material to draw the volatile matter that is not in liquid form but directly sublimates, leaving behind charcoal. This process has doubled the production of energy density of original material because, charcoal is ½ the weight of the original biomass, having the same amount of energy. The charcoal, containing hydrocarbons that burn with black fumes and dirt smelt at much higher temperature than the original biomass, turning it more useful for manufacturing processes, especially in the road engineering. Specialized pyrolysis techniques have been developed to store the volatiles that may be dangerous to the remaining setup. These collections of volatile product generate enriched hydrogen (H₂) gas, a potential fuel and carbon monoxide (CO). These compounds are then commercialized into methane, methanol, and other hydrocarbons in alcoholic form.

Digestion

Biomass digestion works by using biological anaerobic bacterial micro-organisms. The micro-organisms live at the bottom of swamps or at places having no supply of air. These are overwhelming dead organic matter used to produce methane gas (CH₄) and hydrogen (H₂) gas. These bacteria are then fed by organic material like wastage such as, animal dung or human sewage into tanks, called digesters.

The emitted gas is used to store for its utilization as an energy carrier. This process is a very resourceful means of emission of usable energy from such biomass. Generally, up to 2/3 part of fuel energy of the animal dung could be recycled. Another important technique that is related to this process is to collect methane gas from landfill regions. A large quantities of household biomass waste are the kitchen leftovers, lawn cutting and trimming, leaves the wastage materials. After a long life of decades, anaerobic bacterial organisms at the bottom of the tips of digesters could decompose organic matter, including the hydrocarbons and emit methane gas. This gas is then extracted from digester tanks and is used by covering the landfill site with a strong layer of clay. When perforated pipes are injected, then these pipes would collect the gas and bring it to the surface.

Biomass Energy

Advantages of Biomass Energy

There are certain advantages that encourage the bio-mass to be used for further processes. Biomass energy is an eco-friendly and pollution free source of energy. It does not emit CO₂ gas that causes global warming. The same amount of CO₂ is absorbed as the same is released. The main advantage of biomass energy is the use of the same apparatus to produce electricity. It does not affect the environment as the other conventional methods have adverse effects like oil spillage, acid rain, mine spillage, open spitting, radioactive disposal and other wastage produced. Bio-fuels are sustainable. The green methods are used to produce the bio-fuels. So, the rate of carbon is not increasing in the atmosphere. These biomasses are not costly and easily available. They can be grown easily in any area of the world. Alcohol obtained by this process is reliable and can be produced easily.

Disadvantages of Biomass Energy

The cost of construction of the biogas power plant is high, so only advanced cities can utilize them. Continuous supply of biomass is required to generate biomass energy. Biogas plant requires space and produces dirty smell. Transportation of bio-fuel through the long pipes is difficult. Due to improper construction, many biomasses plants are working inefficiently. It leads to the increasing rate of deforestation, soil erosion and desertification.

Conclusion

In this review article the energy resources, types and methodology and their advantages and drawbacks have been discussed. The energy generated from biomass and sea water in the form of electricity is also discussed. The energy production from the biomass and removal of waste materials from the polluted environment is an eco-friendly process. The methods of digestion, pyrolysis, gasification, etc., are described for the electricity generation from seawater. Moreover, hydro process by utilizing sea water for electricity production is also discussed and their advantages and disadvantages have been highlighted.

Introduction

In this age of globalization, media communications and social media, almost everyone is well familiar with the concept of greenhouse effect. The natural process that warms the earth's surface is known as greenhouse effect. The enhanced greenhouse effect is likely to boost the earth's average temperature by 1.0–3.7°C during the next century, leading to changed regional climates, increased global rainfall and a rise in sea levels [1]. There are certain gases, such as water vapor (H_2O), carbon dioxide (CO_2), methane (CH_4), and ozone (O_3), which actively contribute in the process of greenhouse effect. Few more gases and compounds such as nitrous oxide (N_2O) and artificial chemicals such as chlorofluorocarbons (CFCs), also take part in greenhouse effect. The range of share of individual gases causing the greenhouse effect is given in Table 1.

While the share of N_2O and CFCs can reach maximum value of 11%. The share of each contributor gas varies in certain ranges, and probably there is no exact percentage of the share of each gas contributing in the greenhouse effect. This is because of the reason that few gases absorb and emit the radiations at same frequencies and other gases. So, it cannot be said that the total greenhouse effect is the addition of the share of each gas [2]. The issues we are facing nowadays is an increase in the negative effects of greenhouse gases and the volume of these gases generated by human activities. The human activities mainly include but not limited to the burning of fossil fuels, agricultural activities, industrialization, transportation, etc. The increase in the emission of greenhouse gases substantially increases the effects on the earth's ecosystem, thereby creating the disturbance in the normal equilibrium life on the earth at website provided in "Relevant Websites section". Since, the greenhouse gas, especially CO_2 is emitted from various man-made activities, and it is difficult to determine the amount of these gases emitted by individuals, organization or a group of people. Carbon footprint is a term that can be used to measure the total amount of CO_2 released by individual's activities. In this way, the carbon emissions can be measured from individual sources [3]. Once the sources of CO_2 emission can be identified and measured, the values obtained can be used to develop the future energy plans. In this way, the greenhouse gases and carbon footprint can be reduced significantly, which is also an intention of this module.

Greenhouse Effect: Is it an Unending Process?

It is well known process of warming up the earth surface temperature by some of the radiations which are reflected to the space back and trapped into the greenhouse gases. Although this subject was discovered a long time ago, even though it has been the topic of much discussion nowadays. This is owing to the deleterious effects of global warming due to the greenhouse effect [4]. This reference module's intention is to make aware of all the communities of society regarding the understanding of greenhouse gases, their sources, effects and remedies. Therefore, it is of utmost importance to know how this process takes places and affects the climate of the earth. The step-wise process of greenhouse effect is illustrated in Fig. 1.

The greenhouse gases trap the extra heat and warm the global temperature and cause the global warming. These gases are listed in Table 1 along with their individual range of share contributing to global rise of temperature. There are various sources of greenhouse gases, such as CO_2 emitted from combustion of fossil fuels (natural gas, oil, coal and wood), solid waste incineration, production of cement, fertilizers, decay of biomass, forest fires, and deforestation, etc., at website provided in "Relevant Websites section". The sources of methane emissions are production, transport and distribution of natural gas and oil, mining of coal, agricultural activities, and decomposition of organic solid waste. Similarly, nitrous oxide and CFCs are also emitted from agricultural and industrial practices respectively. Among these greenhouse gases, CO_2 is a major cause of global warming even though the range of contribution is lower than that of water (Table 1). Water is available in larger quantities as compared to CO_2 . However, the residence time of water vapors in the atmosphere is quite weak. Therefore, water vapors are not considered when measuring greenhouse emissions. On the contrary, CO_2 emitted from variety of sources remains for a very long time, therefore considered as a major source of greenhouse effect at website provided in "Relevant Websites section". The topic of CO_2 emission as a source of global warming has remained a burning issue since long time. It is evident from the literature that a lot of efforts have been continuously carried out to minimize the CO_2 emission. Until today, it is not clear that how much amount has been spent for the alleviation of CO_2 emissions. This implies that the communities are aware of the harmful effects of greenhouse in the form of global warming. Some of the most understood effects are climate change which leads to the potential ecological, physical and health impacts, including extreme weather conditions, floods, storms, droughts, heatwaves etc. These effects have also been noticed recently in various countries including United States of America, United Kingdom,

Table 1 Range of contribution of various gases in greenhouse effect

Greenhouse effect contributor gas/compound	Range of contribution (%)
H ₂ O	36%–72%
CO ₂	9%–26%
CH ₄	4%–9%
O ₃	3%–7%

Note: Kiehl, J.T., Kevin, E., 1997. Trenberth Earth's annual global mean energy budget (PDF). Bulletin of the American Meteorological Society 78 (2), 197–208.

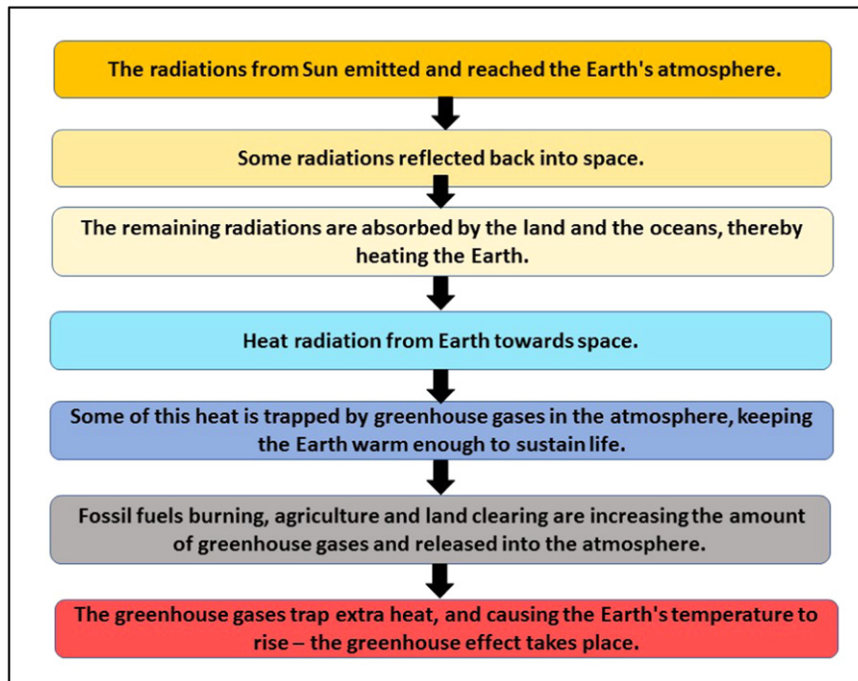

Fig. 1 Step-wise process of greenhouse effect. Data used from Australian Government, Department of the Environment and Energy. Available at: www.environment.gov.au/climate-change.

Ireland, Indonesia, China, etc. Other notable effects are sea level rise, disruption of carbon cycle and water systems, and irregular growth of crops, etc. [5,6]. Despite the enormous efforts made by government organizations, private firms, stakeholders and public for the reduction of CO₂ emissions, still it is not clear how long it will take to completely combat this issue. To date, no time line is suggested or recommended for its complete remediation.

Greenhouse Gases: Timeline Matters

The different greenhouse gases have different timeline to stay in to the atmosphere once these are emitted from any source. The gases that have weak residence time, contribute lower in the greenhouse effect as compared to the gases with higher time of residence in the atmosphere. This is because of the reason that the heat trapped by those gases stays longer time in the atmosphere, thereby warming it extensively at website provided in “Relevant Websites section”. The timeline or residence time of various greenhouse gases ranges from few years to thousands of years and is portrayed in Fig. 2.

No gas remains forever in the atmosphere. This is because of various physical, chemical and physico-chemical processes are continuously undergoing in the complex atmospheric system. The details on these systems can also be found elsewhere in the literature. It is obvious from Fig. 2 that the water vapors and ozone stay less time in the atmosphere. CO₂ is third long lived gas in the atmosphere following nitrous oxide and CFCs, therefore, the contribution of these gases is according to their time span in the atmosphere. Based on the above facts, it can be said the CO₂ and other long-lived gases emitted by any individuals or organizations and industries in a day can sustain the environment and remain for too long time. This long time of greenhouse gases remain in the atmosphere and causes the global warming, which can be very dangerous for us and our future generations at website provided in “Relevant Websites section”. Therefore, it is essential to investigate, how to reduce the release of these gases along with their residence time in the atmosphere, so that the effects of global warming can be minimized.

Fig. 2 Timeline of greenhouse gases in atmosphere. Data used from Jean-Marc. Jancovici. Available at: www.jancovici.com/en/climate-change.

Table 2 Greenhouse gases and their respective GWP values

Name of gas	Relative GWP/CO ₂
CO ₂	1
CH ₄	25
N ₂ O	298
Hydrofluorocarbons	120–14800

Source: Intergovernmental Panel on Climate Change, 2007, 2007. Climate Change.

Global Warming Potential

Another most important factor that can be used to understand and control the greenhouse gases is the term Global Warming Potential (GWP). After the lifetime of greenhouse gases, this is very crucial way to measure the radiative power of a gas and its radiation efficiency. In its simplest form, how much the power of the greenhouse gas for emitting the radiation back to the ground. GWP also varies with respect to the type of greenhouse gas. Water vapors, CO₂, methane, nitrous oxide, ozone and CFCs, all these gases have different GWP value. The different values of GWP for various greenhouse gases provide a relative contribution of each gas in global warming at website provided in “Relevant Websites section” [5]. These values can be very useful to establish the policies and strategies to overcome or control the emission of such toxic gases. Similar to the lifetime of greenhouse gas, larger the values of GWP, the larger will be the contribution of that gas to the global warming at website provided in “Relevant Websites section”. The GWP values of various greenhouse gases are given in Table 2. It is obvious from Table 2 that the GWP of CO₂ is quite lower than that of methane gas. As an example, it can be stated that the methane gas has 25 times more potential than that of CO₂. The other relative comparison can also be made based on the values given in the table.

Based on the GWP values, an assessment can be made on what sources of these high potent greenhouse gases that can be controlled and or minimized.

Carbon Footprint

The contribution in the emission of greenhouse gases at individual level is best described by the term carbon footprint. It is a notion that describes a person's each activity that generates greenhouse gases. The emission of these gases varies greatly from one individual to another depending upon the activities carried out by them [3]. The routine activities of every individual greatly vary, so does their carbon footprint. These activities range from driving a car, travelling in the fossil fuel vehicles, aero planes to the use of domestic equipment at home. Other important factors which reduce the amount of individual's carbon footprint are habits of people, their culture, choices and geographical locations, etc. Like the GWP, carbon footprint is also very important notion of measuring the individual's emissions and contribution to the global warming because it helps to identify the exact sources of populations from where the gaseous emissions are generated in bulk quantities [3] at website provided in “Relevant Websites section”. Once, those sources are identified, the control and mitigation strategies are easier to implement at website provided in “Relevant Websites section”.

Table 3 Categorical ways of reduction of greenhouse gases and carbon footprint

<i>Reduction category</i>	<i>Ways of reduction</i>
Energy	● Sensible use of energy ● Change the light bulbs to LEDs ● Unplug unused electronic appliances ● Turn off the pilot flame of gas furnace in summer ● Turn off lights when you leave the room ● Buy energy efficient appliances ● Clean fridge and freezer coils ● Low wattage equipment/appliances ● Use rechargeable batteries ● Use of renewable energy resources ● Clean AC filters regularly ● Conceal your cooling/heating rooms ● Insulate the walls where necessary ● Operate AC at 26°C ● Use sleep mode on computers when inactive
Water	● Use a reusable water bottle ● Take shorter showers ● Use less hot water ● Limit the water for garden ● Installation of drip irrigation system ● Don't let your water running continuously ● Install low flow rate water sinks ● Use less detergent for washing etc. ● Wash your car in the garden ● Limit your water games/water plays etc. ● Don't defrost food with running water ● Harvest rain water
Food	● Buy food from local sources ● Limit your groceries as per your needs ● Prepare your own compost ● Grow your own gardens ● Buy seasonal food/vegetables and fruits ● Donate excessive/leftover food ● Lower the use beef/lamb and dairy ● Be more vegetarian ● Eat at sustainable restaurants ● Store the food properly to avoid spoilage ● Cooking more at home ● Eat less/as per health requirement
Travelling	● Use mass transit/carpool/public transport ● Combine trips and travelling ● Take fewer long way travels ● Use video conferencing/distance learning where possible ● Avoid flying on private jets ● Avoid flying for short distances
Driving	● Drive smartly and smoothly ● Go for scheduled tuning of engines ● Try driving low carbon vehicle ● Walk or ride bicycle when possible ● Buy low power vehicle or as per need ● Avoid unnecessary speeding ● Use properly inflated tires ● Try avoiding traffic routes ● Try driving on highways/fast routes ● Remove excessive weight from your car ● Limit unnecessary trips and car races ● Avoid unnecessary long mileages ● Prefer hybrid fuel cars ● Prefer to use bikes in bike-friendly routes ● Limit the purchase of unnecessary cars

Table 3 Continued

<i>Reduction category</i>	<i>Ways of reduction</i>
Clothing	● Use a sun light to dry your cloths ● Use full load of cloth cleaning in machines ● Recycle old cloths where possible ● Donate old clothes to charity ● Buy sustainable manufactured clothes ● Avoid over purchasing of clothes
Living style at home	● Chopping by hand ● Avoid minimum use of electronic appliances ● Use environment-friendly colors at home ● Sensible use of air conditioning and heating ● Keep ice maker turned off when not in use ● Avoid too many decorative lighting ● Avoid putting hot objects in fridge/freezer
Community/public	● Attend events that support environment ● Join a club for environmental grooming habits ● Support local environmental legislation ● Contact elected officials ● Awareness workshops ● Plant maximum trees ● Support local business
Education	● Educate yourself ● Teach/educate others regarding the environmental issues ● Introduce educated documentaries for all aged population ● Provide training for environment-friendly practices at home, offices, etc.
Miscellaneous	● Use email instead of paper mail ● Mechanical pencil usage ● Recycle your papers mails ● Print both sides of paper ● Use recycles paper where possible ● Try using non-toxic products everywhere ● Use wash cloths instead of paper towels ● Use hand kerchiefs in place of tissues ● Use digital books and reading materials ● Purchase recyclable toys ● Don't use bad chemicals on your garden ● Use refillable containers ● Use white/chalk boards which are erasable ● Refill the lighters ● Recycle ink jet cartridges ● Upgrade your computer instead new buying ● Buying and consuming needful stuff

Ways to Reduce Greenhouse Gases and Carbon Footprint

There are so many ways to reduce, minimize and alleviate the emissions of greenhouse gases, suggested by various researchers, scientists and engineers. Also, the ways are suggested to implement the policies and strategies for the same purpose. This module consolidates various ways categorically in a tabular form to reduce the toxic emissions of greenhouse gases.

When we Get Rid of all This?

Knowing the history of greenhouse gases and its effects in terms of global warming since very long time, it can be concluded that the reduction in greenhouse gases at significant levels (250–350 ppm) may not be possible for few more centuries. A marginal reduction may be noticed in recent future only if the appropriate remediation measures would be exercised at every stage of emission source. However, since the data varies from time to time, and from region to region, therefore, it is hard to predict the time when the earth will stop overheating by greenhouse gases. This is because of the technological advancements, social, cultural and regional changes in the inhabitants of earth.

It is mentioned elsewhere that if the use of fossil fuels stops today, it would still take many decades to level off the concentrations of greenhouse gases [7]. Although, much efforts are taken to exercise and implement the ways of reduction of greenhouse gases mentioned in Table 3, however, it is still difficult to balance the situation. Therefore, the ultimate recommendation is to continuously optimize the efforts that are made for the minimization of greenhouse gases emissions as much as possible. This is to ensure that the future generations would be able to live happy and safely without the bad consequences of our today's activities that increases the greenhouse gases emissions [8,9].

Judgements and Future Directions for Mitigation of Greenhouse Gas Emissions

The effect of greenhouse and carbon footprints can be limited and mitigated with certain measures. These measures have a certain cost which can constitute the economic value in reducing impact of greenhouse gases. The best and wise decision would be to reduce energy consumption which has been utilized in various forms from electricity generation, transportation, industrial zones, commercial and residential sectors. This could be possible with the transformation of lifestyle and behavioral change of human beings that favors the resource conservation. In addition, the reduction in wastage would greatly contributes in mitigating the release of greenhouse gases. The physical products that are being consumed requires the primary energy to produce and dispose. Therefore, limiting needless products and processes should be encouraged. Besides, plantation would be the great way to revive the natural life cycle. Since, plants absorbs CO₂ gas and help reduce earth's surface temperature. The promotion of mitigation measures can be exercised through carbon price that can establish incentives for producers and consumers to invest in products, processes and technologies notably which may limit emissions below the current levels.

Above all, the first and foremost step toward the mitigation of the greenhouse gases emissions should be the strict implementation of related policies. All the stakeholders, including government, industrialists, practitioners, engineers, scientists, social workers, law makers, and public should involve themselves extensively in the practices that reduces the emissions. The people of all age groups should be trained to exercise the environmentally friendly activities at all walks of life. They should be realized that this globe is not only for you and your kids, rather it is also for your future generations. Furthermore, the extensive attention should be given on the conservation of nature such as plants and forests because of their good capacity to provide carbon sinks. Besides, the global coordination regarding the mitigation of carbon emissions need to be enhanced to support the underdeveloped and developing countries to implement the strategies and exercise the policies and norms. Based on the above judgements and future directions, it would be manageable to find a way out of the serious issues of global warming caused by greenhouse gas emissions.

Introduction

Our earth is one part of the universe that occupies seventy-one percent of water and only twenty-nine percent of land, where human life exists. The water part of earth exists in the form of oceans, sea, rivers, glaciers, lakes, canals and for domestic purposes. Out of seventy-one percent of earth water, only nine percent is used for domestic chores (Granovskii *et al.*, 2008). Most of the ocean and sea water is salty. To utilize this sea water there are many different methods including reforming of fossil, cracking of gasoline products, and electrochemical processes etc., Dincer and Acar (2015). These methods are cost effective and power consuming in the range of mega volts. The hydrogen evolved by these processes was used for conversion of unsaturated hydrocarbons into saturated hydrocarbons like vegetable ghee to vegetable oil. Hydrogen produced from the photocatalysis and plasma is not costly. Further, it provides more energy and fuel that has become the need of every person in this modern era of life. The hydrogen gas at cathode is collected by using catalyst. On the other hand, chlorine gas is toxic for human life, plants and animal (Jiang *et al.*, 2010; Madsen *et al.*, 1996). The reaction of oxygen with chlorine gives rise to chloride oxides, being toxic and injurious, it could cause of air pollution (Mizeraczyk and Jasiński, 2016; Vos *et al.*, 2018). The technology of hydrogen energy production is divided into three categories: at small level availability of hydrogen, at medium level availability and at large level availability of hydrogen production and consumption (Bergman, 2010). It is based on the quantity of hydrogen produced during a process. When natural gas reacts with plasma path, it changes to hydrogen and coal. The formed coal was found in the form of carbon black, composed at the surface, while hydrogen is in gaseous state (Yu *et al.*, 2012). The Table 1 shows some reactions of hydrogen synthesis method to change the renewable fuel sources and production of higher energy means by using the various methods of green synthesis for evolution of hydrogen. The different energy sources are strongly dependent on thermal and/or solar. The hydrogen evolution based on photocatalysis is measured in g/(Wh) to kg/(kWh) at the cost of one dollar to two dollars (Chaubey *et al.*, 2013). In this method, the photocatalyst is added in salty water with particular amount, in the presence of photovoltaic light and under some typical condition of temperature and pressure, which results in the formation cations (sodium ions) and anion (chloride ions). The chlorine gas may react with aqueous solution of hydrogen and form hydrochloric acid. To overcome these kind of problems, the metal oxide catalysts could be used. The manganese oxide is used as an anti-oxidizing agent to shield out the chlorine gas and thus on the other electrode hydrogen gas has to evolve. The reaction of hydrogen evolved by the processes is treated with nitrogen to form ammonia and this ammonia when reacted with carbon dioxide turn it into hydrocarbons, that is, in the form of fuel as given by the reaction. When the evolved H₂ gas is treated at high temperature, it changes into ionic form (plasma formation), which exhibits temperature of millions kelvin.

Significance of Hydrogen Plasma Evolved From Seawater

The fuel cells may be upgraded to hydrogen-based plasma fuel cells and could be useful in the engines of vehicles and many other combustion applications. The price, now a day, for hydrogen fee kilogram is about 2\$ in America and 3\$ in developing countries. The cost of the hydrogen-based plasma produced from seawater is around 1\$/kg. Therefore, the need to find out hydrogen sources

Table 1 Some useful methods to create hydrogen

Energy sources	Hydrogen generation method	Sources	Overview of the methods
Electrical energy	Electrolysis	Water	By electro chemical reaction the water decomposition takes place, thus, by passing electric current the O ₂ and H ₂ are evolved
	Plasma arc decomposition	Natural gas	Cleaned methane gas is passed through electrical discharge plasma to produce hydrogen and carbon soot
Biochemical energy	Dark fermentation enzymatic	Biomass	Anaerobic fermentation in the absence of light
Electric + Photon	Photo-electrolysis	Water	Photo electrodes + electric energy

Note: Kalamaras, C.M., Efstathiou, A.M., 2013. Hydrogen production technologies: Current state and future developments. In: Proceedings of the Conference Papers in Science, vol. 2013. Hindawi.

has increasing day by day. Numerous efforts are in process and plasma researchers are finding the more resources for evolution of plasma hydrogen (Hsu *et al.*, 2018). Energy produced by this method can work at 6 K and is useful in any environment because as it has no toxic or hazardous effect on environment (Nicoletti *et al.*, 2015).

Methodology for Generation of Hydrogen From Sea Water

There is variety of processes that are for hydrogen production and limited methods for production of hydrogen-based plasma and only a few are finding the hydrogen plasma by the sea water. The hydrogen evolved by these processes is utilizing indifferent domestic chores and different energy producing and utilizing sectors. The methods and techniques are given as:

- (1) Hydrogen-based plasma releasing by vaporization of fuels in the form of liquid and gases.
- (2) The production of hydrogen through Au@ZnO zinc oxide composites incorporating different amounts of gold nanoparticles.
- (3) Tentative results are obtained by using experimental findings and observations.
- (4) The process of electrolysis using nickel iron carbide by salty water.
- (5) Plasma hydrogen producing by using catalyst of Bismuth vanadium oxalate in the presence of sunlight.
- (6) Various techniques used for hydrogen evolution by plasma characterization.
- (7) Hydrogenated plasma by green synthesis.
- (8) Other experimental methods-based on hydrogen-based plasma.

Hydrogen-Based Plasma Evolution by Volatizing Substances

The strength of energy for a plasma reaction is defined as the minimum power consumed in equilibrium in a method under considerations. Total heat content known as enthalpy of the system is denoted by ΔH . The rate of this reaction is determined by the consumption rate of reactants. 100% efficient material corresponds to low consumption rate. The strength of partial equilibrium for plasma discharge is less than 20% (Nicoletti *et al.*, 2015). This system of plasma production Consist of different parts i.e., apparatus to get rid of combustion elements, a gas discharge source, plasma producing device for phase of matter transfer to the ionization source, annealing process device and a fuel jet assembly for evolution of plasma into blister assembly. In addition to above parts a secondary gas source takes exhaust and optical detecting device is also part of this system. The oxygen and hydrogen through SEM or TEM is observed. The process is carried out in the presence of hydrogen or carbon with low value dielectric materials. This process is carried out for different exhausting gas for example:

- (1) The exhaust gas of hydrogen and oxygen from combustion burner in plasma gadget are conducted. The noble gas that is non-reactive is introduced at the level of 7000 cm range at typical atmospheric pressure is introduced. The photoresist on the substrate is heated at temperature of 300°C. The hydrocarbon material is combusting ionized at the preheating temperature. in early stage no plasma formation takes place. Oxygen gas is evolved at 1000 cm supply. But it does not take place in the glass chamber. The exhaust of hydrogenated plasma with hydroxide ion takes place after a long time and it is occurring within vacuum chamber. This experimental result is drawn by the plasma slag process. The resulting peaks represents that the different hydrocarbons are combusted with different behavior. But, this hydrogen can be utilized into the chamber and cannot be exhaled from the system to be used for other applications.
- (2) Using the above apparatus set up the carbon dioxide gas is observed by using an enduring gas inventor like plasma invention in burner.

Hydrogen Generation Using Catalyst Under UV-Technique

The production rate for hydrogen may increase by adding the amount of Au in catalytic material, at the cathode. The evolution of hydrogen depends on the amount of gold and surface area of the catalyst when it was irradiated at 400 nm UV radiation. The solution was characterized by 100 mL of salty water including the brine solution into a reactor beaker. As a catalyst, 50 gm of Au was added to this flask. For opposing the corrosion, the sacrificial reagents were used in the form of Na₂S and Na₂SO₃ in adequate amounts. The resulting solution is heated at 20°C, with magnetically focalized nitrogen at 20 rpm. The prepared solution can be irradiated by the UV-light for two hours under suitable wavelength. The hydrogen may be produced at the nitrogen electrode and is demonstrated by gas chromatography. If the amount of gold is increased, then the production of hydrogen can be increased. In collaboration of the USA, Japan and many European countries, better result is expected in the coming days. Table 2 illustrates the weight percent of Au@ZnO corresponding to surface area.

The maximum amount of hydrogen by this process was determined to be 550 $\mu\text{mol/hg}$ under UV-radiation of 320 nm with gold weight of 10%. Thus, the evolution of hydrogen was 6 times higher than the commercial hydrogen. But, when it is irradiated at 400 nm wavelength of light, then the production of hydrogen is 8 times higher than the commercial generation of hydrogen. The production of hydrogen at the wavelength of 400 nm is higher than the wurtzite gold particles with 10% weight of gold (Wu *et al.*, 2014; Chen *et al.*, 2012; Flis-Kabulska *et al.*, 2015). The hydrogen-based plasma evolution from fuels can derived by using various methods such as using electron beam having specific aperture lenses, creating barrier of dielectric igniting discharges,

Table 2 Characterized surface area of Au@ZnO catalyst for the experiment

Catalysts	ZnO commercial scale ($\text{m}^2 \text{g}^{-1}$)	ZnO nanoparticles ($\text{m}^2 \text{g}^{-1}$)	ZnO nanowires ($\text{m}^2 \text{g}^{-1}$)
Bare catalyst	18	67	167
1% Au	22	70	174
3% Au	23	73	183
5% Au	25	77	184

Note: He, W., Kim, W.K., Wamer, W.G., *et al.*, 2014. Photogenerated charge carriers and reactive oxygen species in ZnO/Au hybrid nanostructures with enhanced photocatalytic and antibacterial activity. *Journal of the American Chemical Society* 136, 750–757.

Fig. 1 Two steps for hydrogen generation using catalyst and plasma. Reproduced from Wang, L., Yi, Y., Guo, H., Tu, X., 2017. Atmospheric pressure and room temperature synthesis of methanol through plasma-catalytic hydrogenation of CO₂. *ACS Catalysis* 8 (1), 90–100.

skating, Laval nozzle devices and microwave. There are some reactions that results in plasma production as shown in Eqs. (1)–(8). The energy drawn during these reactions in eV/(molecule's. KJ/mol g (H₂)/kWh) is shown in following reaction (1)–(8).

Auto thermal reforming Methane

The first two steps for the evaluation of hydrogen are shown in Fig. 1. The most important task is to find out the hydrogen-based plasma from hydrocarbons reforming. The plasma produced by methane reforming is analyzed over electron beam radiolysis spark igniters microwave gas ionization. Methanol and ethanol are used as a feedback with dielectric discharges, surface ion discharges in the form of Aurora Borealis. The cost of energy based on hydrogen production yield is 2\$/kg of hydrogen. These technologies are widely used for production of hydrogen.

The energy production rate will be higher when the liquid fuel is used as source of hydrogen production. When the catalyst used there are many chances to produce other processes energy rather, but it is just a prediction not an experimental proof

(Jones *et al.*, 2010). Since, plasma method is suitable for production of hydrogen under low cost rate. The plasma generating 5 years ago, yields the energy power of about 60 g H₂/kWh. But, this method requires high energy requirements with high relying. So, possible advancement in the producing of hydrogen-based plasma is a necessary step to produce high yield at low cost.

Nickel Iron Carbide as Electrolysis Process From Seawater

In this process, aluminum matrix with electron deposits is used. The hydrogen evolution process in Ni-Fe-C is measured in the form of current density of the order of 200 A/m². At the evaluation point the potential observed is about only 65 mV at the pH 12. The rising demand of amount of fuel, the hydrogen can be suitable for energy in the next few years (Winand, 1994). The electrolysis process is still considered an effective method for Hydrogen production. Sea water that is consisting of NaCl in the form of brine is an electrolytic solution. The ions that are, sodium ion Na⁺ and Cl⁻ ions are responsible for electrolysis process. The tides in sea water are providing the power for electrolysis and thus for evolving of hydrogen. For this mechanism the cost is higher, due to this reason use of catalyst to improve the electrolysis process is mandatory. For this a transition metal like nickel is used. Ni is best for its usage in hydrogen evolution system due to low price and a reactive transporter in the reaction of hydrogen evolution. Since all the requirements of good catalyst are found in nickel (Kim *et al.*, 2014; Cullity and Stock, 2001). At different pH values of solution different I value shows the electrolysis process for brine solution. The hydrogen concentration is 3.5% weightage in the salty solution at 65 mV at pH value of 12 at temperature about 90°C in 60 min.

Generation of Hydrogen From BiVO₄ under Solar Energy

The method to produce hydrogen from sea water, that is, solution of brine that contains NaCl is an interesting and vast field of plasma science. Since, there is no device that can measure the energy at high scale which is one of the requirement of the process. To fulfill this demand, BiVO₄ was used as a source of energy. Bismuth vanadate is nanomaterial derived from the Bismuth related particle. The hydrogen that may be used as an energy source, can be used as a fuel in the future at low cost. The natural sun source and natural water are the greatest source for production of energy at large scale. Different resources used to synthesize the other artificial materials and the purpose of catalytic reactions was achieved. The abundance of seawater and the presence of high level salinity is the main motivation behind the process of production hydrogen by using the salty (Bakony *et al.*, 1996; Santato *et al.*, 2001). There is not any stable process yet available to split up water in the sea by absorption of photo light beside the process of bismuth vanadium (BiVO₄) oxide and poly metal oxide element. The current density of light for this process is used in the order of 2.16 mA, and the solar energy of the order of 1.5 g. The photo anode is operated in the visible region. BiVO₄ based solar system have been invented in which, BiVO₄ is doped with molybdenum transition metal. The resistivity of molybdenum metal is lower due to which it is used to increase the photo current and enhanced dispersion. When RhO₂ is used as catalyst with it, it increases further the photo current and increases the stability of light in saline water containing 3.5% NaCl. This catalyst is necessary to encourage the usage of molybdenum impurities with BiVO₄. There are bubbles of hydrogen and chlorine gas at the cathode and

Fig. 2 BiVO₄ nanophotocatalysts dual doping for hydrogen evaluation. Reproduced from Jo, W.J., Kang, H.J., Kong, K.J., *et al.*, 2015. Phase transition-induced band edge engineering of BiVO₄ to split pure water under visible light. *Proceedings of the National Academy of Sciences of the United States of America* 112 (45), 13774–13778.

anode since chlorine gas is more absorbed in water than hydrogen. Chlorine gas is highly oxidizing than hydrogen and it has more pH than hydrogen of the order of 6–7. When chlorine gas interacts with water, hypo chloric ion is formed. Due to smaller conductivity of BiVO_4 , a doping process is used that enhances its photocurrent and photochemical efficiency for production of hydrogen through saltwater. The nano particles for BiVO_4 are very stable and are widely used to remove the impurities from the waste water emitted by the industrial terrestrial sources contaminated with toxic impurities (Long *et al.*, 2008; Wang *et al.*, 2013; Zhou *et al.*, 2008; Sarkar and Chattopadhyay, 2012; Mitev *et al.*, 2015). Fig. 2 shows the dual doping of bismuth vanadate nanoparticles used for hydrogen evaluation.

Hydrogenated Plasma by Green Synthesis

Hydrogen evolution is necessary tool overcome the limitations of the greenhouse gases, that's why, it is called green synthesis (Ambrosio *et al.*, 2018; Lin *et al.*, 2013; Gharbi *et al.*, 1982). Recently, methane gas is characterized to produce hydrogen resulting in emission of greenhouse gases. Steam reforming also produces about 30% hydrogen gas from oil and 18% from coal. Water electrolysis also yields 3.8% hydrogen gas. In future, the green methods will be applicable to produce hydrogen on commercial scale. This hydrogen may be useful in producing artificial fuel, NH_3 and fertilizers with saturated hydrocarbons (Yu and Kudo, 2005; Nagabhushana *et al.*, 2013).

Conclusion

Here, numerous methods were investigated for the production of hydrogen-based plasma as a green energy using biological, chemical and physical approaches. However, each method has its merits and demerits that limit their frequent use to produce hydrogen at industrial scale. The hydrogen produced from photocatalysis and plasma based seawater is pollution free and non-toxic. The fuel derived by this method can be extended its limit up to 70%. The significance of hydrogen plasma evaluated by seawater, hydrogen evaluation under UV and solar light in the presence of catalyst is also reviewed.

Introduction

Fresh and clean energy is the basic need of our era but due to the rapid increase of population and industrialization of the globe, it would be very difficult to provide the energy equally. The demand of energy has increased from 17 TW to 27 TW within the last 30 years (Huang *et al.*, 2013). In the near future, it would be a challenging task to fulfill these requirements of energy because resources of fossil fuels are decreasing and may cause a pollution in air and environment. Since hydrogen energy was found to be efficient and clean, numerous sources have been adopted for hydrogen evolution including fossil fuels, fractional oxidation, coal-gasification, auto thermal reforming, electrolysis and by consuming the steam reforming through natural gas (Tahir *et al.*, 2017a). The hydrogen generated from fossil fuels and others may cause emission of harmful gases like CO₂, CO, etc (Xia *et al.*, 2014). Practically 85% energy can be exchanged by the fossil fuels which, disturbs our atmosphere and assets also. It also changes the configuration of our atmosphere upsetting weathers and human health (Mai *et al.*, 2013). Therefore, the production of green energy has become thrilling need to modern era of technology. Photocatalysis was found to be more efficient approach to produce hydrogen through splitting of water.

Photocatalytic Hydrogen Evolution Through Water Splitting: Mechanism

In this method, due to the presence of sunlight, water molecule breaks into the hydrogen and oxygen. The general form of water splitting reaction is given as

A large amount of energy is absorbed to perform this reaction that is $\Delta G = 237.1$ kJ/MOL at the STP and at the 1.23 V of thermodynamic potential (Tahir *et al.*, 2017c). Previously, different devices were in use for the advancement reaction of hydrogen and oxygen, however currently a single device involves with both evolution reactions; one is at cathode and other is at anode. The evolution reactions for hydrogen and oxygen are given as (Amoo and Fagbenle, 2014):

The above reactions cannot take place without photo-catalysts.

Hydrogen-Evolution Reaction (HER)

The hydrogen evolution reaction involves many steps given by the following equations:

Eq. (1) is Volmer step, Eq. (2) is a Heyrovsky step and the Eq. (3) is known as Tafel step. There are two cases for the evolution reaction of hydrogen; in the 1st case, Volmer and Heyrovsky steps are involved while in the 2nd case, Volmer and Tafel steps are involved. In both cases, the amount of energy that is ΔG is absorbed to perform this reaction and hydrogen is absorbed by the electrodes that release it in the form of hydrogen gas. The rate of this reaction directly changes with bonding strength of atoms and ΔG . As the surface bonds are weak, less amount of energy is required and reaction would occur rapidly but in the case of strong surface bonding large amount of energy is needed that slows down this reaction (Tang *et al.*, 2011). That's catalyst was used to enhance the evolution of hydrogen and these catalyst decreases the value of ΔG . The materials that may be used as catalysts for this hydrogen evolution reaction may be alloys of nickel (Ni), oxides and phosphides of metals.

Catalytic Requirement for HER

Hydrogen production and evolution reactions are usually slow types of reactions. It means that it takes long period of time (Wang *et al.*, 2017). To increase the rate of reaction and to decrease the time of these reaction occurrences, different types of

catalyst such as molybdenum sulphides, molybdenum carbides, molybdenum nitrides and molybdenum phosphides etc, were used (Yan *et al.*, 2013). However, here the effect of molybdenum sulphides catalyst due to its outstanding activity and constancy on hydrogen evolution reaction in their nanoparticles form has been reviewed. Nanoparticles are the microscopic particles that have dimensions in the range of 100 nm or less than 100 nm (Duan *et al.*, 2015). Most of the time, the properties of nanoparticles are different as compared to their bulk molecules form. Molybdenum sulphides catalysts are regularly manufactured at a high temperature and particular optimal experimental conditions (Gholamvand *et al.*, 2016). The procedure could be exorbitant and vitality escalated. The undefined MoS_x (x = 2, 3) films were incredible hydrogen development catalysts. As for the MoS_x films created, the manufacture technique represents a limitation in the functional usage of these impetuses: the layers must be prepared by electrode position at 0.3–0.8 V versus SHE (Standard Hydrogen Electrode). Anodes and cathodes which are not stable in such an electro-chemical gap are subsequently not appropriate substrates (Zheng *et al.*, 2014). Numerous semiconducting and non-directing substrates can-not be utilized not one or the other. The weaknesses of the MoS_x thin films can be survived if the nebulous MoS_x impetuses can be delivered artificially and in a huge amount. Different affidavit techniques would then be able to be connected to gather the impetuses onto an extensive variety of substrates. In this, the compound readiness of shapeless MoS₃ nano-particles and their reactant movement for hydrogen evaluation reaction have been discussed (Seo *et al.*, 2015).

MoS₂ as a Photocatalyst

MoS₂ has many interesting characteristics like it can be used as a lubricant, as a catalyst for HE reaction and as a transistor in two dimensions. Tributsch was the first person who worked on the catalytic effect of MoS₂ in its bulk form and he observed that this is not energetic in its bulk structure. After that by using the suggestions of their colleagues, they utilized the MoS₂ in the form of nanoparticles and then they observed that it was very reactive at its smaller level (Yang *et al.*, 2016). Molybdenum disulphide is highly closely packed structure like graphite. It has large number of surfaces inside it with the distance of 6.5 angstrom and providing the path for the motion of electrons and holes. The sheets of Molybdenum disulphide are perpendicular to each other (Dong *et al.*, 2015). Due to its large number of sheets and surfaces in its bulk structure, it has expressed inertness towards the reaction. But due to its activity even as nanoparticles, it was used as a catalyst to speed up the hydrogen evaluation reaction.

Molybdenum Tri-Sulfide as a Catalyst

The properties of molybdenum trisulphide, its production and comparison with molybdenum disulphide have been discussed.

Production of MoS₃ and Their Characteristics in Amorphous Form

Indistinct MoS₃ particles are regularly arranged via fermentation of tetrathiomolybdate resolutions. It was observed that MoS₃ can be of endless supply of MoO₃ and Na₂S making the combination more practical (Zhou *et al.*, 2016). For typical synthesis of material, molybdenum trioxide MoS₃ (1.0 g, 6.95 mmol) was dissolved in distilled water and sodium sulfide (8.34 g, 34.74 mmol of Na₂S·9H₂O in 250 mili-Litter of water) for the preparation of gel like solution. That arrangement was then held below enthusiastic mixing while the 6.0 mole solution of HCl was added gradually (approximately 10-min) until-the solution reached a value of pH 4. Then the prepared solution was placed under observation for an optimal time and it was found that significant amount of H₂S has been produced in vapor form (Mahler *et al.*, 2014; Zhao *et al.*, 2013; Hosseini *et al.*, 2017). After this, the whole suspension was bubbled for 30-min to remove the H₂S and to enhance the filtration-step. The solution was then cooled at room temperature and washed with water and ethanol. The glue like suspension obtained was mixed with 1.0 L of (CH₃)₂CO in an Erlenmeyer cup and stirring was performed for 30-min. After this, it was sonicated for 5-min through ultrasonic-horn at 20 kHz. A very clear dark solution was obtained and placed 3 days for precipitation (Tahir *et al.*, 2017b; Zhang *et al.*, 2014). It was then dried for 12 h at 80°C after purification and crushed MoS₃ was formed.

Production of Molybdenum Sulphides C-Paste Electrodes

The terminal of carbon's surface was cleaned by testing paper. The prepared powdered MoS_x particles were squeezed at carbon glue terminal and were extended equally by utilizing paper (MoS_x incorporates MoS₃, MoS₃-350, MoS₂-650, and MoS₂). The commercial MoS₂ particles were observed to be crystal-like. There are some specific conditions which make it (MoS₃) possible to utilize as a catalyst for the given reactions (Benck *et al.*, 2014). The electrode of carbon paste was prepared with 80:20 ratios of graphite and paraffin wax respectively and was not found to be able for the performance of hydrogen evolution until by taking composition with thin film of molybdenum trisulphide nanoparticles (Vrubel *et al.*, 2012). This kind of reaction was found to occur at the 17 mA cm⁻² current density within 60 min. It shows the excellent activity and stability of molybdenum trisulphide.

Activity of Crystalline Molybdenum Sulphides as a Catalyst

By using the chemical reduction process, molybdenum trisulphide cannot be directly reduced into the molybdenum disulphide. There are different methods that are used to form the molybdenum disulphide (Yan *et al.*, 2014). At the temperature of 350°C, the molybdenum trisulphide is converted into the MoS₃-350 by increasing the 1 µm size of the material within the time of 60 min. By using the same techniques, MoS₂-650 was obtained at 650°C within the time of half an hour. For the reaction of hydrogen evolution, these MoS₃-350 and MoS₂-650 are passed through the carbon-blank-paste. Both of these are least reactive catalysts (Zhang *et al.*, 2015). But the molybdenum disulphide does not activate in the reaction even when the potential is greater than two hundred million volts. But there is no such type of condition with molybdenum trisulphide; it is very reactive even at its lower potential. Here it was found that the activity of molybdenum trisulphide is payable to the occurrence of sulphur atoms in the material. These sulphur atoms make bonds with hydrogen atoms in the evolution reaction of hydrogen and separate it from the hydrogen to form the hydrogen gas H₂. As the molybdenum trisulphide has crystalline structure, so by increasing the particles number in the crystals, crystallinity of the material is increased. The activity of molybdenum trisulphide has inverse relation with concentration of particles in the crystals. Therefore, by increasing the particles' numbers, reactivity of molybdenum trisulphide catalyst decreases and vice versa (Benck *et al.*, 2014).

Cobalt as a Co Catalyst for Molybdenum-Trisulphide

It was revealed that shapeless MoS_x layers were stored on an operational anode, e.g., ITO or lustrous carbon, only when a watery arrangement of (NH₄)₂[MoS₄] was focused to successive repeated voltammetry experimentations. The MoS_x layers were dynamic hydrogen evaluation reaction impetuses. It was observed that a thin film was likewise saved from a fluid arrangement of (NH₄)₂[Co (MoS₄)₂] in a comparative electro-polymerization system (Wang *et al.*, 2012). Complex-1 is a very much characterized Cobalt complex that was recently prepared as a nitrogenase enzyme model. Investigation by XPS revealed that the film surrounds Co, Mo, and S. In this manner, complex-1 fills in as an atomic antecedent for the ternary metallic sulfide-layering. Moreover, it is conceivable to practice in situ arranged 1, framed promptly upon the blending of CoCl₂ with (NH₄)₂[MoS₄], as the antecedent. The proportion of Cobalt to Mo isn't restricted to 1:2 in the statement shower. The Co– Mo– S films are dynamic hydrogen evaluation reaction impetuses. To recognize the ideal proportion of Co to Mo in the affidavit shower, various films were set up on a polished carbon anode from arrangements in which the fixation proportions of CoCl₂ to (NH₄)₂[MoS₄] shifted between 1:200 and 1:2. At the point when the proportion surpassed 1:2, a precipitation was seen after blending of CoCl₂ and (NH₄)₂[MoS₄], so no endeavor was made to store films from such blends. The polarization bends of the Co–Mo–S films at pH equal to 7 and 0 can be demonstrated. The Co²⁺ particle advances the reactant action of nebulous MoS₃ (Zhang *et al.*, 2015).

Conclusion

In the current article, the detailed description on the green approach of hydrogen evolution, its fundamental aspect and mechanism and hydrogen-evolution reaction has been discussed. Comparing with the pristine molybdenum sulphides based nanoparticles, the modified nanostructures were observed to be more efficient and showed an outstanding photocatalytic hydrogen efficiency. Further, the improved efficiency could be attributed to the upshifted conduction band edge, higher surface area, narrowed bandgap and efficient transfer and separation of charge-carriers. The newly developed photocatalytic nanomaterials will be more beneficial for energy harvesting potential application.

Introduction

Pulping and Pulping Processes

Pulping is a process of defibration of lignocelluloses into individual fibres. It is done by mechanical and or chemical processes. Chemical wood pulping involves the extraction of cellulose from lignocelluloses by dissolving the lignin that binds the cellulose fibres together. Four processes principally used in chemical pulping are kraft, sulfite, neutral sulfite semichemical (NSSC), and soda. The kraft process is the predominant process in the world. In the kraft process, sodium hydroxide and sodium sulfide used in water as cooking chemicals at higher temperature. The cooking chemicals are known as white liquor. This process is flexible to raw materials.

Pulping and papermaking process includes: Raw material preparation and handling, Pulp manufacturing, Pulp Washing and Screening, Chemical recovery, Bleaching, Stock Preparation, and Papermaking.

Pulp is produced from lignocellulosic biomass, which includes hardwood, softwood, non-wood and recycle fibres. Hardwood and softwood are the dominant raw materials for pulping.

What is Jute?

Corchorus sp is a bast fibre obtained from dicotyledonous plants of the Genus *Corchorus* and family Tilaceae. It is an annual renewable fibre crops grown mainly in Bangladesh, India and other Asian countries. Conventionally, the bast fibre is extracted from plants by a natural microbial process known as retting. Retting has been used for a long time in case of extraction of fibres from jute plants. In general, the practice of retting jute plants in the jute growing regions is to immerse the jute bundles in clear slow flowing water in canals, tanks, ponds or ditches. The minimum ratio of plant material to water in stagnant water should be 1:20. Retting and extraction processes have a profound effect on the quality of fibre produced, and on the cost of fibre production. It affects the efficiency of manufacturing, the quality of the end products and their competitiveness in the market. The conventional retting requires 14–28 days to degrade the pectic materials, hemicellulose, and lignin (Paridah *et al.*, 2011). Conventional retting process is not environmental friendly and requires large amount of water. Therefore, Bangladesh Government has introduced ribbon retting method in different areas of the country to ease peeling of jute fibre. Fig. 1 shows conventional and ribbon retting of jute.

Jute is one of the cheapest textile fibres and used widely in the manufacture of different types of packing materials for various agricultural and industrial products. Once it was known as “Golden fibre of Bangladesh”. The export of jute and related products accounts for a significant portion of total export in Bangladesh. In addition, it provides considerable employment opportunities to the country's work force. Traditionally, jute is being used in sacking, gunny bag, hasein, etc. In recent years, jute has faced hard competition from synthetics. Therefore, traditional uses of jute have declined. As a result, its demand in local and overseas markets has declined. Therefore, diversified usage is needed to regain the lost glory of jute.

In this article, evaluation of jute pulping in respect to raw material handling, process selection, and product development is discussed.

Chemical Composition

Jute fibres have three principal chemical components, namely, α -cellulose, hemicelluloses, and lignin. The lignin can be almost completely removed by chlorination, and the hemicelluloses are then dissolved out of the remaining holocellulose by treatment with dilute alkali. The final insoluble residue is the α -cellulose constituent. Many research papers have been published on the chemical constituents of jute. Jahan *et al.* (2007a,b) showed that retted jute fibre constituted with 63.1% α -cellulose, 13.5% pentosans, 12.7% Klason lignin along with minor amount of extractives and ash. As shown in Table 1, jute fibre is characterized with higher α -cellulose and lower lignin than hardwood and softwood. The α -cellulose and lignin content in jute stick is close to softwood. The hemicelluloses consist of polysaccharides of comparatively low molecular weight built up from hexoses, pentoses, and uronic acid residues. In jute, *Corchorus capsularis* and *Corchorus olitorius* have similar analyses, although small differences occur between different fibre samples. The average molecular weight of the hemicelluloses is in the range of 24,000–27,000. Jute fibres contain a proportion of acetyl groups, which are readily hydrolyzed by dilute alkali to acetic acid. Soutar and Bryden (1955) have reported acetyl contents averaging 110 for hibiscus, 89 for *C. capsularis*, and 76 for *C. olitorius*, all expressed in milliequivalents of acetic acid per 100 g of dry fibre. The higher acetyl content of *capsularis* than *olitorius* has since been confirmed by Manzoor-i-Khuda *et al.* (1970). Acetyl content is a very important parameter for prehydrolysis step in producing dissolving pulp (Li *et al.*, 2010). Acetyl content generates free acetic acid during prehydrolysis process, which facilitates hemicelluloses dissolution (Saeed *et al.*, 2012; Jahan and Rahman, 2012; Jahan *et al.*, 2013a,b).

Fig. 1 Conventional and ribbon retting of jute (a) conventional retting, (b) ribbon extraction, (c) ribbon retting.

Table 1 Chemical constituent of jute along with hardwood and softwood

Raw material	α -cellulose (%)	Lignin (%)	Hemicellulose (%)	Reference
Jute fibre	63.1	12.7	13.5	Jahan <i>et al.</i> (2007a,b)
Jute stick	39.6	25.9	18.2	Rahman <i>et al.</i> (2016)
Hardwood (Sugar maple)	45.0	22.0	17.0	Pettersen (1984)
Softwood	37.2–41.5	29.1–32.6	18–21.9	Mcdonough <i>et al.</i> (2001)

The chemical composition and fibre properties of different parts are different. Different stages of the growing season also affect the chemical composition and fibre properties of the plant tissue. It was seen that the fibre length at the middle part of both the bastfibre (bark) and core (stick) was longer than the top and bottom part. Shafi *et al.* (1993) showed that jute bast fibre was longest at a distance of about 75 cm from the bottom of jute plant. With increasing height from bottom to top lignin content

decreased and α -cellulose content increased. Consequently, the paper making properties of the pulp obtained from jute at different portions of jute is expected to vary. Jute follows the same morphological pattern as in the case of wood/tree. It is well agreed that wood exhibits the longest fibres at a distance of about one-third to one-half of the tree height (Panshin and Zeeuw, 1980). The bottom and the top of the tree possess the shortest fibres (Hale, 1969).

The jute bastfibre has higher α -cellulose and lower lignin than core (Jahan *et al.*, 2008b). Rowell and Stout (1998) noted in his book article that the University of Manchester, the Shirley Institute and the British Textile Technology Group in the United Kingdom have spent years working on jute. While some of the research findings have been published, the results relating to the changes in the properties of jute fibre as a function of the growing season were done for the International Jute Organization in Bangladesh, but were not published. Personal communications concerning these results indicate that juvenile jute fibre looks and feels like silk, but this has never been documented in print. Chatterjee, working at the Technological Jute Research Laboratories in Calcutta, India, first reported the changes in chemical composition at different stages of jute plant growth (Chatterjee, 1959). These results show that there is little difference in cellulose, holo-cellulose, and the lignin content, but the content of xylan, ash, and iron decreases as the plant matures.

Mukherjee *et al.* (1986) also studied characteristics of the jute fibre at different stages of growth. It was observed that there was an incomplete formation of the middle lamella in the cell wall at the early stages of growth and the parallel bundles of fibers were oriented at an angle with respect to the fibre axis that gradually decreased with growth. After about 35 days of growth, the fibrils run parallel to the fibre axis. In the mature plant, a few helically oriented fibrils were observed in the 2-direction just below the primary cell wall layer. Clark and Wolff (1969) found that the pentosans, lignin, and α -cellulose content increases with age. Data taken from the top part of the plant shows similar trends; however, the top part has less cellulose, pentosans and lignin.

Effect of ribbon retting on the chemical properties of jute fibre and jute stick was studied by Jahan *et al.* (2016). Pentosan, extractive and ash content in ribbon retted jute fibre and jute stick were higher and lignin and α -cellulose content were lower than the conventional retted jute fibre and jute stick. These differences were pronounced for jute stick. The differences in chemical characteristics of core and bark fibre of jute at different position -top, middle and bottom were studied (Jahan *et al.*, 2008a). With increasing height from bottom to top lignin content decreased and α -cellulose content increased. The bark (fibre) had higher α -cellulose and lower lignin than core (stick) (Table 1). The bark produced nitrobenzene oxidation products with larger syringaldehyde/vanillin (S/V) ratios than the core. The yields of nitrobenzene oxidation products in bark were higher than core. The analysis of neutral sugars suggested that xylose is the predominant sugar of hemicellulose in both bark and core. The bark had higher glucose and lower xylose as compared to core.

Pulp Making

A brief description on pulping has been mentioned in Section 1.1., it is done by mechanical and or chemical processes. Most of the studies of jute pulping were carried out on chemical processes. Therefore, in this article, pulp making is discussed on chemical process only.

For chemical pulp, logs are first chopped into wood chips which are then cooked with chemicals under high pressure. Cooking removes lignin and separates the wood into cellulose fibres. The resulting slurry contains loose but intact fibres which maintain their strength. During the process, approximately half of the wood dissolves into what is called black liquor. The cooked pulp is then washed and screened to achieve a more uniform quality. The black liquor is separated out from the pulp before the bleaching process. Black liquor is evaporated and burnt in recovery boiler and generates heat and recover cooking chemical by causticizing. Bleached pulp is sent to paper machine. The detail process flow diagram is shown in Fig. 2.

Fig. 2 Pulping process flow diagram.

Table 2 Properties of pulp from jute and other raw materials

Raw material	Process	Pulp yield (%)	Kappa number	oSR	Tensile index (N m/g)	Tear index (mN m ² /g)	Burst index (kPa m ² /g)	Reference
Jute fibre	Soda-AQ	64.2	10.7	31	53.1	21.2	5.5	Jahan <i>et al.</i> (2013a,b)
	AS-AQ	65.5	16.9	31	53.5	22.2	6.3

Softwood (pine)	Kraft	46.6	35	383	119	11.7	10.3	Hatton and Gee (1994)

Pulping for Papermaking

The basic density of wood influences the pulp production. The density of jute fibre is 1400–1500 kg/m³. The density of jute fibre is higher pulpwood (Casey, 1980). As for example, wood density of mangrove species was within the range of 562–643 kg/m³ (Al-Maruf and Jahan, 2015). The higher wood density certainly produces more pulp produced per digester (Goyal *et al.*, 1999). This result indicates that jute fibre gives a significantly higher packing factor, producing more pulp per digester.

Chemical constituents of jute indicate suitability for pulping. Therefore, many studies have been carried out on jute fibre, jute stick and whole jute plant pulping in different processes conventional kraft and soda processes as reviewed by Akhtaruzzaman *et al.* (1991), Akhtaruzzaman (1994), Akhtaruzzaman and Shafi (1995), Akhtaruzzaman (1998), Shafi (1994) in home and abroad. The conventional kraft and soda processes produce pulp with low yield with inferior strength with several processing problems. There have been attempts in the manufacturing of chemical grade pulp from jute by the conventional soda process in Sylhet Pulp and Paper Mills since seventies. But it failed due to severe lumping of pulped material in the digester, difficulties in washing and screening and more seriously due to drastic loss in pulp strength on bleaching. The process also leads to low pulp yield (Anon, 1988). Studies were then conducted with conventional kraft process. But the situation did not improve to a noticeable extent (Bhowmick, 1988).

Jute fibre produced higher yield and lower kappa number than whole jute plant and jute stick (Table 2). This is due to higher α -cellulose content and lower lignin content in jute fibre (Rahman *et al.*, 2006). Alkaline sulfite anthraquinone methanol (ASAM) process showed very high pulp yield (61.5%) and low kappa number (7.6) from retted jute fibre (Jahan *et al.*, 2005a,b). The papermaking properties and bleachability of the produced pulp was very good. But the process needs high pressure vessel, which will increase capital investment. This will also increase operating cost (Table 2).

Akhtaruzzaman *et al.* (1991), Akhtaruzzaman (1994), Akhtaruzzaman and Shafi (1995), Akhtaruzzaman (1998), Bose *et al.* (1999), Shafi (1994) conducted extensive studies and reported on the suitability of jute in respect pulping process, economics, problems of jute pulping etc. The authors showed that the neutral sulfite anthraquinone (NS-AQ) process was very promising for jute fibre pulping. It eliminates the problems encountered in the alkaline processes. In addition, this economically feasible process produces pulp with higher yield and conifer-like kraft pulp, with regard to physical strength properties. These append that despite higher cost of jute, highly demanding costly pulp can be produced from retted jute fibre. But little studies were conducted on bleaching.

Jahan *et al.* (2013a,b) re-verified soda- anthraquinone, (soda-AQ), alkaline sulfite- anthraquinone (AS-AQ) and neutral sulfite-anthraquinone (NS-AQ) pulping processes for jute cutting and caddis. The jute mill do not use bottom part of jute fibre (due to inferior properties), this part is called jute cuttings; in addition, jute caddies obtained as rejects in jute mill. A photograph of jute cutting and jute caddis is shown in Fig. 3. The NS-AQ process showed favorable pulp yield and kappa number for both these raw materials: 66.1% for jute cutting and 59.9% for caddis at a kappa number of about 11. The physical properties of NS-AQ pulps were also better than those of soda-AQ and AS-AQ pulps. At °SR 44, the tensile index of NS-AQ pulp was about 100 N m/g for jute cuttings and 70 N m/g for caddis, while their tear index was almost similar. All these pulp were bleached by D₀E_pD₁ bleaching sequences. The NS-AQ pulp showed excellent bleachability and its brightness reached to 89% for jute cutting and 85% for caddis using a total chlorine dioxide of about 15 kg per ton. After bleaching, the strength properties of NS-AQ pulp were slightly better compared to soda-AQ and AS-AQ pulps. The differences in pulpability of core and bark fibre of jute at different position were studied (Jahan *et al.*, 2008a). Under identical conditions of pulping, bark gave higher pulp yield and lower kappa number than core. Lower kappa number signifies higher delignification degree. The bark pulp showed better bleachability than core pulp. The higher tensile index in core pulp and higher tear index in bark pulp were observed.

Effect of ribbon retting on kraft pulping was studied (Jahan *et al.*, 2016). Pulp yield of conventional retted jute fibre and jute stick was higher at any kappa number. The variation of papermaking properties of the produced pulp on retting process was insignificant. The bleachability of jute fibre pulp was better than that of jute stick pulp. Conventional retted fibres showed slightly better bleachability. Jute fibre pulp consumed 15 kg ClO₂/MTof pulp to produce brightness of 81%–86%, while jute stick consumed 30 kg ClO₂/MTof pulp to produce brightness 85%.

Organic acid pulping of jute has also been evaluated for papermaking. It was observed that pulp yield was very good and easy to bleach by total chlorine free bleaching, but papermaking properties were not acceptable level (Jahan *et al.*, 2007a,b; Sahin and Young, 2008). It was also seen that hemicelluloses were dissolved along with lignin in the pulping, causing reduced fibre bonding during sheet formation. Acetylation and formylation of hydroxyl group of cellulose were another possible reason of lower papermaking properties (Jahan *et al.*, 2007a,b). Sahin (2003) pulped jute fibres by ethanol-alkali (EtOH-NaOH) process. The

Note: Hurler, A.M., 1991. Nonwood plant fiber progress Report No.19, Tappi Press. Quoted by Akhtaruzzaman, A.F.M., 1994. Market Prospect for Pulp and Paper from Jute, Kenaf and Sisal and Appropriate Technology and Marketing Strategies FAO These Products, ESC: JU/EGM 94/5. Rome: FAO.

delignification proceeded more rapidly and selectively with ethanol-alkali than alkali alone. Pulp yield and strength properties were better than soda alone.

Pulping of whole jute plant also has been studied in different processes (Jahan and Farouqui, 2000; Jahan *et al.*, 2000; Jahan and Farouqui, 2001; Jahan *et al.*, 2005a,b). Pulp yield obtained was 51% at kappa number 28 in kraft process (Jahan and Farouqui, 2000). In that study ethylenediamine (EDA) or monoethanolamine (MEA) was used as additive with soda liquor. The pulp yield is considerably higher than for the control soda and kraft pulps. Pulps obtained are better in physical properties compared to kraft and soda pulps. As shown in Table 1, pulp yield in ASAM process was 56.6% with kappa number 39.2, but the papermaking properties was very good (Jahan *et al.*, 2005a,b).

Jute fibre pulp bleached to very high brightness (88%–90%) with the consumption of 7.6 kg ClO₂/ton of pulp (Jahan *et al.*, 2010).

The papermaking processes from jute in some cases are superior to conifer pulps (Akhtaruzzaman and Shafi, 1995). Such pulp can be used to make specialty papers that cannot be readily produced from wood pulps. This can also be used as additives to impart some special characteristics that cannot be used by wood pulp alone. The possible end uses of jute pulp are noted in Table 3.

Blending of Nonwood Pulp With Wood Pulp

In papermaking, it is very often that more than one type (or grade) of pulps are used to develop paper sheet properties necessary for both machine runnability and requirement of the end users. In many paper grades, long fibres from softwood bleached kraft pulp are often used in combination with short fibre from hardwood bleached kraft pulp (HBKP). In this combination, the long fibre component provides the strength (especially tear resistance) to the paper sheet, while the short fibre helps to improve the paper functional properties, such as sheet smoothness and formation. It is generally accepted that fibres such as straw are not likely to be used on a 100% basis for paper manufacturing. Particularly their poor drainability and low tearing strength make it necessary to use furnish mixtures containing a certain amount of long fibres. Jute has longer fibres and other non-wood in Bangladesh have shorter fibres. A very good tensile-tear ratio is observed in case of jute pulp. Whereas corn stalks, kash, dhanicha, straw, etc. produced pulp of high tensile strength. So jute pulp can be used as reinforcing fibre for other nonwood pulps. Jute fibre provides long fibre furnish, where cotton stalks, corn stalks, straw and other nonwood fibres available in Bangladesh provide short fibre furnish. It was observed that the blending of corn stalks pulp with jute pulp increased tear strength (Islam and Jahan, 2001). Tschimer *et al.* (2003) showed that a significant increase in tensile and burst strength with an addition of soda-AQ wheat fibre to the hardwood/softwood mixture typically used in printing and writing grades. The tear index of dhaincha pulp was improved with adding jute pulp (Jahan *et al.*, 2007c). Therefore, there is a good possibility in Bangladesh to set up integrated pulp (separate fibre line for different characters of fibres) mills based on nonwood fibres, which will solve the scarcity of fibrous raw materials and contributes an environment friendly atmosphere.

Dissolving Pulp

Jute fibre is an expensive lignocellulosic fibre. Its α -cellulose content is very high and lignin and pentosan content are low (Table 1). These are advantageous for producing dissolving pulp production.

Jute fibre, jute cutting and jute caddis were evaluated in producing dissolving pulp by prehydrolysed kraft process (Jahan *et al.*, 2007a,b). In that study it was observed that rayon grade pulp could be produced from jute fibre, cutting or caddis. Jute fibre produced dissolving pulp having 90%–97% α -cellulose (Jahan, 2009). Organic acid process dissolved both lignin and hemicellulose simultaneously (Jahan *et al.*, 2007c). Therefore, jute fibre, jute cutting and jute caddis were also evaluated for dissolving pulp production in organic acid process (Jahan *et al.*, 2008b). The α -cellulose of the produced pulp in organic acid process was 90%–97%. The pulp bleached up to 87% brightness in total chlorine free bleaching. High purity dissolving pulp were also produced from jute fibre by prehydrolysed kraft pulping followed by fractionation and alkali extraction (Nayeem *et al.*, 2017). Fock reactivity increased with decreasing fibre size, but α -cellulose content in long fibre fraction was higher than that of short fibre fraction. Fock reactivity of pulp indicates its ability in xanthation reaction. Alkaline extraction further removed pentosans resulting in increased α -cellulose content in the pulp. Fock's reactivity also increased after reduction of hemicelluloses by weak alkaline extraction. Formic acid treatment followed by alkaline extraction and $D_0E_pD_1$ bleaching produced pulp of 94.3% purity with Fock's reactivity of 63.2%. Alkaline extraction of the bleached pulp increased purity to 97% with Fock's reactivity of 72%–73% (Nayeem *et al.*, 2017).

Dissolving pulp was also produced from jute stick by pre-hydrolysis kraft process (Matin *et al.*, 2015). The pulp yield was 36.2% with kappa number 18.5 at the cooking conditions of 16% active alkali as Na_2O for 2 h of cooking at 170°C. The prehydrolysis was carried out at 170°C for 1 h of pre-hydrolysis. Final pulp was produced with 92% α -cellulose and 89% brightness after $D_0E_pD_1$ bleaching, which could be used in rayon production.

Supply and Storage of Jute for Pulp Making

Jute is a non-conventional raw material for pulping. Therefore, for the development of jute pulp mill, it is immense attention on jute supply and its delivery is very vital. Jute pulp mills project needs to know the growth, harvesting, collection, transportation and storage aspects of jute. Thus, critical analysis of supply and storage of jute has enormous importance in setting a jute based pulp mill.

A sustained supply of fibrous raw material (FRM) to the mill site and its effective storage are important parameters for consideration of setting a pulp mill. Akhtaruzzaman (1998) extensively discussed on the storage and supply of jute for pulping. In case of jute, it is altogether different from round wood and saw mill chips that it is a seasonal crop. Jute is traditionally cultivated by the farmers in the land which cannot normally be used for other crops. It is mainly grown for the retted bastfibre which brings immediate cash to the farmers during the lean period. In extracting the bast fibre on retting, the woody core is obtained as the by-product. The core is largely used by the villagers as fuel and in making thatched house and for fencing. As a result, the value of the core is in no way less important than the bast fibre. Thus, use of jute stem or core may create social problems in countries where there is an acute scarcity of fuel and thatching materials, unless alternatives are given to the villagers. Jute is cultivated in small patches of land scattered at different localities. Its stem and core are very bulky.

Conventionally, they are costly to transport over long distances. The situation is further aggravated because the harvesting time falls in the monsoon when normal vehicular transportation in many jute growing areas becomes more difficult and expensive. The odd harvesting time also makes drying of the stem in the field impossible in many cases.

In this situation when the stem is collected and transported in the green condition with approximately 70% moisture, the transportation cost can be a large component of the total cost of production.

Conventionally, a pulp mill does not own a large area of land to grow jute. Then naturally the mill may not have a direct control over the cost of fibrous raw material (FRM). This situation may become worse in case of crop failure due to perennial weather changes. In order to avert these problems in the supply position, the mill may plan to grow jute itself in leased land in adjoining areas to meet the mill demand. It seems to be too optimistic. Jute cultivation by the mill authorities using hired land and labour, management and inputs, etc., may turn it into an expensive venture.

Therefore, the supply situation of jute stem and core must be seriously taken into account in considering them as pulping FRM. It is a fundamental problem that has to be overcome for the viability of a mill.

Jute stem and core are susceptible to rapid fungal decomposition causing severe damage to the fibre. Because of their high bulk, they are difficult to store. It is reported that kenaf stem (a material similar to jute stem) even if compressed to high density bales of 500 kg/m³, the volume of storage for one year supply of the stem is about 217,000 m³ for a 50,000 ton/year chemical pulp mill (Wong, 1991). With a stacking height of 3 m, a stacking width of 3 m and a stacking space of 3 m, the estimated storage yard needs a space of 150 hectares (373 acres). This space should be under cover. Many developing countries may not afford to arrange such a large space under cover for storage. Even then there remains the chance of hazardous attack by termite and powder post beetles. Thus, the storage problems alone can act as a cognizable limitation and demand a serious consideration in pulping of jute stem and core. The problems must be scientifically assessed and solved if these materials are used as the FRM. With such multiples of problems in the supply and storage of jute stem and core, naturally the question arises whether jute has at all any prospect to be used in pulp industry. The situation is entirely different when the bast fibre is considered. The collection and transportation mechanisms of retted jute bast fibre are well accepted by the jute fabric mills. The farmers bring the dried material in hand-pressed bundles to the selling centers or markets. The practice continues for months together after harvesting. So the problem of patch collection from the farmer's field or home immediately after harvesting as is usual for the stem or core is done away with. The density of the retted bast fibre is reported to be 1500 kg/m³ (Joseph, 1980) against 185 kg/m³ for the stem (Islam and Khan, 1984). This means a large advantage in transportation and storage of the bast fibre. The dried fibre is resistant to micro-organisms and insects (Joseph, 1980). Thus its storage has been well practiced in sheds by the jute fabric mills with no serious problems. Therefore the supply and storage problems of the FRM with the bast fibre are substantially minimized. This is a strong point in favor of its use as a pulping raw material. However, the cost of the material may be questionable. The lower grades of jute (bast fibre) and jute cuttings which are low priced have little use and can serve as the FRM in pulp making. These grades of jute amounted to about 250,000 tons annually in Bangladesh (Akhtaruzzaman and Shafi, 1995). Encouragingly, these fibres can yield pulp superior to conifers (Akhtaruzzaman and Shafi, 1995). The pulp can then be used in making specialty papers (Akhtaruzzaman, 1994). The FAO expert group meeting on diversified application of bio-resources (FAO, 1994) also concluded that jute bast fibre has the potentiality of making pulp for value-added specialty papers.

Conclusion

Jute fibre is characterized with high α -cellulose (>60%) and low lignin (<15%) content consequently easier to delignify. A very high pulp yield (above 60%) is obtained from jute fibre with low kappa number (10–15). Papermaking properties of jute fibre pulp were exceptionally good. Tensile index of jute pulp reached to 100 N m/g at tear index of about 20 mN m²/g. Jute pulp need less chlorine dioxide to get desired pulp brightness (90% ISO). Neutral sulphiteanthraquinone (NS-AQ) and alkaline sulfite anthraquinone (AS-AQ) processes showed best results in terms of pulp yield, kappa number, bleachability and papermaking properties. Dissolving pulp can also be produced from jute fibre with good purity and reactivity. For dissolving pulp production, organic acid process showed the best results in terms of yield, bleachability (84%), purity (97% α -cellulose) and reactivity (73% fock reactivity). Jute fibre is a seasonal crop, therefore, a good transportation and storage strategies are needed for jute based pulp production.

Introduction

Although sisal plant is found across the world, it grows mostly in the regions of Brazil, Tanzania, Mexico, Africa and china. Normally, sisal plants are not planting in systematic way. It grows along the railroad pathways and beside the water flowing areas of farming fields (Chand and Fahim, 2008). Numerous types of sisal plants are identified all over the world. Agaves are large plants in the sisal fiber family of Agavaceae in which it contains about 300 species such as Agave cantala, Agave guiengola, Agave americana, Agave angustifolia, Agave flexispina etc (Yu, 2005).

Initially, Sisal plant was found in South American and Middle African countries. In 1930s, the Brazil is the first country for harvesting and cultivating the sisal plants, commercially. Later, the other African, European and Asian countries initiated the sisal fiber cultivation and harvesting. Also, the first sisal fiber trading was made in the year 1948 by Brazil. In 1960s, India also joined to cultivate and extract fibers from the sisal plants from southern east states such as Orissa, Andhra Pradesh and Tamil Nadu (Saxena *et al.*, 2011).

The sisal fibers and their products are consumed in the period of 1960–1970 since the production reached 800,000 tonnes. In the recent years, due to the challenge of the man-made fibers and their products, there is reduction in the production and exports. Even though, the sisal fibers are sustaining their direct and indirect products in the real time markets. The major sisal fibers consuming countries are the United States of America, Canada, France, Germany, China and Belgium. These countries are using the sisal fibers in various applications such as high quality papermaking, mining, forestry, metallurgical industries, composite materials, floor casing mattresses, buffs and construction materials (Yu, 2005).

The necessities of research on sisal fiber are (a). It possesses high strength, attraction to dyes and resistance to weakening in sea water, (b). Sisal is the one of the best among all other natural fibers which is simply cultivated, (c). It has excellent recyclability and less renewable times and (d). Sisal fiber and products are eco- friendly.

Properties of Sisal Fibers

Physical Properties

The sisal plant normally yields 50–150 mm thick, sharp, long and closely arranged leaves and is prepared to get yield merely after 2 years of planting (Laxmikanta Nayak *et al.*, 2011). However, the plant matures fully after 3–4 years of growth. The matured sisal leaf is to be identified by the accomplishment of leaf length of about 1 m and also the leaf spike attains the angle of 60° in which the colour of the end spike changed to pale brownish. Typically, a well grown up sisal plant produces 200–250 usable leaves in its entire lifespan of about 12 years. Also, the leaf encloses with 1000–1200 fibers (Yu, 2005).

Sisal plant

The schematic diagram of sisal plant is shown in Fig. 1(a). Sisal plant (Agaves) has a central stem on which the leaves grow up. Their leaf physically appears like a sword and dark green colour. The edges of the leaves are covered with teeth. When it attains maturity period, these teeth will disappear. A typical length and width of the sisal leaf is 1.5 m and 15 cm respectively. Usually, it can be extracted from the fibers which is equal to length of the leaves. That is, the length of sisal fiber is approximately equal to the length of the leaf and the diameter of the fiber is in between 100 and 300 μm (Naveen *et al.*, 2019). The dried fiber weight is just 3%–4% of the leaf weight.

Sisal leaf

The schematic diagram of a sisal leaf is shown in Fig. 1(b). A sisal leaf has 15 cm length and average thickness is 5 cm. A cut section of sisal leaf is shown in Fig. 1(c). The leaf consists of the fiber and moisture. There are three kinds of fibers such as mechanical fiber, ribbon fiber and xylem fiber.

Mechanical Fiber: The fiber is attached to the sisal leaf's periphery. When the leaf is crushed, the moisture in the fiber is removed and fibers are separated. This fiber is called mechanical fiber. It appears like thick-horseshoe shape after the extraction. This fiber will have good strength and can be used for all commercial purpose.

Ribbon fiber: The fiber occurring in the mid span of the leaf is called ribbon fiber and its cross-sectional view is shown in the Fig. 1(c). This ribbon fiber offers mechanical strength to the sisal leaf. This fiber is the longest one compared to other type of the fiber. It can be fragmented longitudinally according to the process requirement.

Xylem fiber: The fiber present at middle of the leaf is called Xylem fiber. It is arranged in irregular manner. It occurs along the latitudinal direction to the ribbon fibers. This fiber gives the shape to the leaf. Since these fibers are arranged in irregular manner, it may be broken while extracted.

Fig. 1 The schematic diagram of (a) sisal plant, (b) sisal leaf and (c) sectioned view of the sisal leaf.

Fig. 2 A cross sectional view of a sisal fiber cell.

Sisal cell

A sisal fiber has more than 100 cells and every cell has a length of 2–5 mm (Naveen *et al.*, 2019). The cross sectional view of a sisal fiber cell is shown in the Fig. 2. Every single cell is linked with other cells through the middle lamellae. The Lamella consists of hemicellulose, lignin and pectin. A sisal fiber cell consists of lumen, tertiary wall, inner secondary wall, outer secondary wall and primary wall. Lumen, the smallest inner part of the sisal cell, is positioned at the centre of the cell (as shown in Fig. 2). The diameter of the lumen is 9–12 μm . The lumen is covered by tertiary wall. The fibrillae is irregularly arranged over the tertiary wall. This tertiary wall is covered by inner secondary wall with a slope of 18° . These walls are attached with hemi-cellulose and lignin matrix in spiral orientation manner. The outer secondary wall lies between the primary wall and inner secondary wall. This outer secondary wall is covered by primary wall with a slope of 40° . This wall is also covered by the cellulose with spiral shape direction. However, cellulose presents on the outer secondary wall is opposite direction to the inner secondary wall.

Chemical Composition

The chemical composition of sisal leaf is shown in the Table 1. It has 60% cellulose, 10% hemi-cellulose, 9% lignin, 7% pectin, 10% moisture content, 2% waxes and 2% ash (Saxena *et al.*, 2011). The sisal fibers have the similar composition of cellulose level with other natural fiber. Alternatively, the presence of lignin content in the sisal fiber is higher than the other natural fiber plants such as jute, pineapple fiber etc. Also, the sisal fiber is stronger and coarser than other natural fibers. It is because of high pectin and lignin content presence in the sisal leaf.

Table 1 The chemical composition of sisal leaf in percentage

Constituents	Values (%)
Cellulose	66
Hemicellulose	10
Lignin	10
Pectin	10
Waxes	2
Ash	2
Moisture absorption	10

**Fig. 3** Tensile strength of the sisal fiber after the aging at different temperature. Reproduced from Chand, N., Fahim, M., 2008. Tribology of Natural Fiber Polymer Composites, first ed. India: Woodhead Publishing.**Table 2** Mechanical properties of sisal fiber

Mechanical Property	Sisal
Specific modulus (approximate)	18
Stiffness (kN mm^{-1})	30–40
Tensile modulus (GPa)	10–40
Tensile strength (GPa)	540–720
Young's modulus (GPa)	13
Elongation at break (%)	2.2–3.3
Maximum elongation (mm)	5–10

Mechanical Properties Sisal Fiber

The sisal fiber bundles have the greater lignin content. This lignin content in the sisal fiber bundles provides high rigidity and exhibit excellent tendency of strength when compared to other natural fibers. The sisal fibers have the highest stiffness, low density and low compressibility ratio when associated with other natural fibers. Chand and Fahim (2008) evaluated the sisal fiber tensile strength after the different aging treatment. The graphical representation of this result has been given in the Fig. 3. It reveals that the strength of the sisal fiber remains almost equal even after 7 years treatment. The Table 2 provides the mechanical properties of a typical sisal fiber.

Extraction of Sisal Fiber

Usually, ample quantities of fiber exist on the surface of the sisal leaves. These fibers are rooted longitudinally in the leaves. The average weight of a standard leaf is about 600 g and individual leaf has more than 1000 fibers. After the harvesting of the sisal plant, the useful fibers are extracted from the leaves. The process involved for extracting fibers are (1). Retting, (2). Boiling and (3). Decortication.

Retting

It is a method that divides the fiber packs from the leaf stem. In this process, the fibers are released from the fiber crop tissues (Ramesh, 2018).

Boiling

The functional fibers are obtained from the sisal plant by bleaching, boiling, beating, washing and drying with sunlight. This method is suitable only for smaller quantity.

Decortication

It is the mechanical technique for extracting sisal fiber. During this process, the leaves are crumpled between smooth-edged blades. While it is crushed the moisture and the fleshy pastes are eliminated from the fiber. The fiber quality remains the same and it is suited for large scale operations. The residues exist after the fiber extraction can be used as raw material for biogas plant, paper board, wax, polymers and preparing paper.

Sisal Fiber Treatments

Sisal fiber treatments facilitate the adhesion at the interphase between fiber and matrix resin. It increases strength of the sisal fiber embedded in the composites. It also impacts the mechanical and frictional properties of the sisal fiber reinforced composites.

Physical Treatment

A physical treatment changes the structural and superficial properties of the fiber. This treatment affects the other properties of composites. The various methods of physical techniques are heat treatment, plasma treatment, fiber surface coating, electric discharge method, and gamma radiation treatment. These methods are employed to increase the interface bonding and adhesion.

Heat treatment

The sisal fibers will be immersed in the boiling water either with pressure or without pressure for stipulated time period. This treatment helps to improve the cleaning of sisal fiber. Only if the fiber surface is in clean condition, it can react with resin and exhibit strong interface bonding.

Surface coating

Normally, polymeric coating will be done for improving reinforcing character. It enhances flexural strength and thereby flexural modulus. These coating improves the fiber-resin matrix bonding (Venkateshwaran *et al.*, 2013).

Plasma treatment

The plasma treatment primarily causes chemical embedding, engraving, and change of crystal structure. The adhesive property of the fiber is increased by the etching process which enhances physical property like surface roughness. This modified surface roughness aids the adhesion at the inter-phase. The modification of the cellulose fiber carried out by the electric discharge method increases the melt viscosity of the fiber and enhances the other related properties.

Chemical Treatment

The chemical treatments are used to alter the fiber external modification and their interior structure. Some important chemical treatments are (1). Treatment with sodium hydroxide (2). Treatment with salt water and (3). Permanganate treatment.

Treatment with sodium hydroxide

This treatment is a kind of purifying process. The sisal fiber cellulose constituent is not affected by the treatment of Sodium hydroxide. This treatment removes the non-cellulosic constituents like hemi-cellulose, pectin and water solvable constituents. The

Fig. 4 A bar chart represents the strength of the sisal fiber after the sea water treatment. Reproduced from Yu, C., 2005. Sisal. In: Franck, R.R. (Ed.), *Bast and Other Plant Fibers*, first ed. United Kingdom: Woodhead Publishing, pp. 84–107.

ultimate aim of this treatment is to reduce the quantity of gums and lignin in the fibers. It improves their elasticity, quality and elongation at break (Saravanan and Devaraju, 2018). This will increase the spin-ability of the fiber.

Treatment with sea water

To understand the reaction of sisal fiber with salt water, the fibers are immersed in the sea water and fresh water for the different time periods. Fig. 4 represents the strength of the sisal fiber after the sea water treatment. The result reveals that strength of sisal fiber immersed in fresh water decreased drastically. Whereas sisal fiber maintains its almost full strength even after 45 days immersed in sea water (Yu, 2005).

Permanganate treatment

Alkali treatment alters the superficial structure and tensile strength of sisal fiber. The permanganate treatment improves the tensile strength of the sisal fiber. Whereas some other treatment (acetone) decreases its strength because of water absorption.

Bleaching

It is the method of removing non-cellulosic compounds by chemical treatment. Normally, the bleaching is done with sodium chlorite solution about 60°C for 1.5–2 h. This treatment improves the mechanical and physical characteristics. Although the bleaching treatment reduces the tensile strength of the sisal fiber, it exhibits huge bonding strength while preparing the sisal based composite. It improves flexural strength and impact strength. Since lignin is removed due to bleaching process, it exhibits less stiffness and hence it can be rolled easily.

Sisal Fiber Composites

The natural fiber composites play important role in recent decades. Although the research on jute, hemp, banana and palm leaf based composite started long back, the attention on sisal fiber based composites started very recently. The sisal fiber composite replaces a synthetic fiber material in all day to day life. Moreover, the hybridisation of the sisal fiber with other natural fiber such as jute, hemp, and banana, gives the excellent mechanical and tribological properties.

Sisal Fiber Reinforced Polymer

The sisal fiber, normally, absorbs a large amount of water which leads to delaminate failure. Alternatively, when the sisal fiber is reinforced with hydrophobic polymer matrices, it becomes Sisal Polymer Composite (SPC). And this SPC will have poor resistance to water absorption. The SPC can be classified as thermo-set and thermo-plastic.

Table 3 Comparison of thermo-plastic Sisal Polymer Composite and thermo-set plastic Sisal Polymer Composite for different properties

S.No	Properties	Thermo-plastic SPC	Thermo- set SPC
1	Tensile strength	Low	High
2	Flexural strength	High	Low
3	Fatigue strength	Low	High
4	Stiffness	Low	High
5	Toughness	High	Low
6	Water resistance	High	High
7	Synthesis	Addition polymerisation	Condensation polymerisation
8	Reusability	Recyclable, remould /reform after heating	Can not be recyclable and remoulded since it retains the rigidity at high temperatures.
9	Brittleness	Low	High
10	Temperature stability	Low	High,
11	Cost	Moderate	Cheaper
12	Density	Low	High
13	Common resins	PET, polypropylene, polycarbonate, PBT, Vinyl, polyethylene, PVC, PEI, nylon	Polyester resin, Vinyl ester resin, Epoxy, Phenolic, Urethane
14	Melting point	Low	High
15	Rigidity	Low	High
16	Solubility	Soluble in some organic solvents	Insoluble in organic solvents
17	Durability	Low	High
18	Processing methods	Injection moulding, extrusion process, blow moulding, thermoforming process, and rotational moulding	Compression moulding, reaction injection moulding
19	Molecular weight	Low	High

Thermo-set SPC

The thermo-set SPC is fabricated with the resin such as polyester, epoxy and phenol-formaldehyde. It can be prepared by hand lay-up followed by hot compression moulding. This is simple and effective method. The strength of this composite depends on sisal fiber length, percentage of fiber weight, fiber orientation and kind of resins. Addition of nano particles plays important role in mechanical properties of SPC (Devaraju and Sivasamy, 2018). Among aforementioned resin, the phenol-formaldehyde provides better tensile, toughness and flexural properties because of strong interfacial bonding. And also it can be heat treated between 100 and 250°C so that its tensile strength and elongation at break will be improved.

Thermo-plastic SPC

The thermo-plastic SPC normally, is fabricated by extrusion compounding or injection moulding. Since it is fabricated under pressure, sisal fiber length may be reduced due to breakage in the intermediate steps. There are four thermoplastic matrices such as Poly Lactic Acid (PLA), Low-Density PolyEthylene (LDPE), High-Density PolyEthylene (HDPE) and Poly Vinyl Chloride (PVC). The major advantage of thermo-plastic SPC is recyclability. The thermo-plastic SPC can be fabricated with lesser time than thermo-set SPC. The waste products of natural cellulosic fillers are shell flour, wood flour, and pulp. These cellulosic fillers can be used as reinforcement for thermo-plastic SPC (Table 3).

Hybrid Sisal Fiber-Based Polymer

Hybrid composite consists of two or more fibers. Adding sisal fibers into synthetic fibers partially replace synthetic fibers in the Hybrid Sisal based Polymer Composites (HSPC). The HSPC provides the combined properties of their individual constituents. While sisal fibers hybrid with other natural or synthetic fibers, it significantly enhances their tribological and mechanical properties by taking the advantage of their individual constituents. It also reduces the water absorption. Since HSPC have superior properties, it can be used in many applications of engineering and technology.

Tribological Behavior of Sisal-Polymer Composites

Tribological behaviors of sisal fiber are quite interesting. However, a very few researchers (Chand and Fahim, 2008) have attempted to evaluate the friction and wear behaviors of different sisal fiber based composite.

Sisal – Epoxy Composite

Sisal- Epoxy Composites (SEC) are used in car interiors. The tribological test on SEC reveals that abrasive wear takes place when sisal fiber is placed parallel to the sliding direction. Whereas when the sisal fiber is placed perpendicular to the sliding direction, less surface damage occurs. However, SEC exhibits better wear resistance than epoxy composite.

Fig. 5 Various applications of sisal fiber.

Sisal – Phenolic Composite

Sisal- phenolic composites are used in automobile brake pads, linings and couplings. Normally, sisal fiber will easily decompose at higher temperature. But, when sisal fiber is reinforced with phenolic, it withstands the higher temperature applications. Because of that, the sisal- phenolic composites exhibit better friction and wear behaviors at 150°C and 250°C. Furthermore, when sisal fiber content is increased, Sisal- phenolic composites performs much better.

Application of Sisal Fiber-based Composites

Sisal fiber can be used directly as twines, ropes etc. and indirectly, it can be used as sisal embedded composites. **Fig. 5** shows the different applications of the sisal fiber.

Direct Applications

Sisal fibers are directly used in the form of yarn, twine, rope, fabrics, buffs, mattress and floor coverings (Yu, 2005). Sisal yarns are used to make rope or cables. Sisal twines are used for weaving carpets. Ropes are prepared by twisting the twines. Since sisal ropes have anti-slipage properties, cold resistance, abrasion resistance and chemical resistance, it can be used in chemical, mechanical and shipping industries. Sisal buffs are produced from yarns. These buffs are used for polishing the shoes and hand bag design. Sisal fiber can be used as mattress since it has good permeability with moist air and water. Mosquito net can be produced from sisal twine. Also it can be woven as floor and wall covering cloths.

Indirect Applications

The sisal fibers are used in composite. The sisal embedded composite can be used as noise absorber, insulator and impact load absorber. Sisal fiber based composites can be used in construction materials, automobiles, rail engines, and aerospace applications. It is also used in packing and binding material for construction and agriculture industries. Sisal based composites are used as insulating materials in the electrical applications. Since sisal fiber has high specific strength, and processing advantages, it replaces synthetic fibers such as asbestos and glass fiber.

Inorganic fibers (glass, asbestos etc.) have several disadvantages such as (1). Non-bio degradability, (2). Abrasion when it rubs with other parts, and (3). Human health problems during processing, and handling of these fibers. Whereas sisal fibers are biodegradable, it is eco-friendly and less abrasive. Hence, sisal fiber based composites are used as computer casing, cabin lining, acoustic insulation, seat cushions, geo textiles, personal safety equipment, bio gas applications, paper making, sun helmets etc.

Fig. 6 The different types of impact factors of the LCA.

Life Cycle Assessment

Life Cycle Assessment (LCA) is a method to analyse the impact of environmental issues and energy requirements for the different stages of a product (raw material to end life) (Jane Bare, 2009). LCA can be implemented for the various part of the product's life cycle.

Need of LCA

LCA report should be prepared before the start of any factory or introduction of a new product. The different LCA factors have been presented in Fig. 6. This LCA report contains the details of resource requirements such as land, human, energy etc and environmental impacts such as ecological toxicity, acidification, eutrophication, ozone depletion and global warming (Guinee *et al.*, 2011). In addition to that, some sub factors such as fossil fuel depletion, smog formation, water intake, air pollutant etc., are also considered for this analysis. Based on this report only, the appropriate governing body will recommend to the government to start a factory or to permit to introduce a product to the society. Moreover, the LCA will give the detailed knowledge to the manufacturer about the different stages of the life cycle of the product (Young Song *et al.*, 2009).

Methods of LCA

LCA is broadly divided as cradle to grave assessment, cradle to gate assessment and gate to gate assessment (Young Song *et al.*, 2009). These assessments are explained based on the life cycle of the sisal fiber product. As shown in the Fig. 7, the life cycle of the sisal fiber product can be divided into nine stages such as cultivation, harvesting, fiber extraction, treatments, products, composites, applications, decomposing and disposal (Edgar Hertwich *et al.*, 2008).

The *cradle to grave* assessment of sisal fiber is the full life cycle assessment (stage 1 to stage 9). This assessment studies from the sisal plant cultivation to the disposal of the sisal products to the earth. The *cradle to gate* assessment is a partial life cycle analysis. In this assessment, the analysis is done between initial stage (cultivation of sisal plant) and product at the factory gate (yarns, twines, ropes etc). That is in the stage between 1 and 5. The *gate to gate* assessment is the analysis of any one specific stage of a product. For example, fiber extraction (3) is a stage.

Standards of LCA

The LCA study was introduced in the year of 1960s. The main objective of this study was initially limited to the energy analysis. In the period of 1970s, this was broadly extended into the departing approaches, interpretations, terminologies and outcomes. And then, in the 21st century onwards, the LCA was fixed as a mandatory assessment for every product to review the environmental impact analysis and to know the resource requirement. To avoid the confusion and variations among the different methods of the LCA, the ISO introduced a standard during the year 1997, called ISO 14040. Later, after some modifications ISO 14044 was introduced during the year 2006 (Finkbeiner *et al.*, 2006). This standard will give the assessment results of the cradle to grave analysis, cradle to gate analysis and gate to gate analysis. The ISO standards suggested four stages of LCA studies. They are goal definition and scoping, inventory analysis, impact assessment and interpretation of results (Mansor *et al.*, 2019). Guinee *et al.* (2011) suggested that, in addition to the LCA, the Life Cycle Sustainability Analysis (LCSA) will also be done to know the complete details about the technical relations and product associated difficulties including environmental impact analysis.

Fig. 7 The different stages of the life cycle of the sisal fiber.

Fig. 8 Comparison of different LCA factors between Tanzania and Brazil (a) land occupied (ha yr^{-1}), (b) Depletion of fresh water ($\text{m}^3 \text{t}^{-1}$), (c) Depletion of Non-Renewable Energy (NRE) (GJ t^{-1}), (d) percentage sisal plant used as Renewable Energy (RE) (GJ t^{-1}), and (e) emission of Greenhouse Gas (GHG) ($\text{kg CO}_2 \text{eq. t}^{-1}$) Reproduced from Broeren, M.L.M., Dellaert, S.N.C., Cok, B., *et al.*, 2017. Life cycle assessment of sisal fiber – Exploring how local practices can influence environmental performance practices can influence environmental performance. Journal of Cleaner Production 149, 818–827.

LCA on Sisal Fiber

Many researchers have evaluated the LCA study in different natural fibers such as hemp, flax, banana, cotton, china reed, jute and kenaf fibers (La Rosa *et al.*, 2013; Finnveden *et al.*, 2009; Zhou *et al.*, 2018; Venkateshwaran and Elayaperumal, 2010). However, as far as current researcher knowledge is concerned, no researcher has attempted for the complete LCA study (cradle to grave approach) on sisal fiber and its products. Broeren *et al.* (2017) conducted the cradle to gate LCA analysis on the sisal fiber. The outcomes are compared to the glass fiber and other natural fibers.

The land occupied, depletion of fresh water, depletion of Non-Renewable Energy (NRE), percentage sisal residues used as Renewable Energy (RE) and emission of Greenhouse Gas (GHG) are compared between Tanzania and Brazil. These data are presented in the Fig. 8. The occupation of the agricultural land in Brazil is higher than Tanzania for same quantity of sisal fiber production (Fig. 8(a)). Since the essential soil nutrients such as potassium, magnesium and urea are naturally present in the Tanzanian soil, Tanzania occupies lesser land than Brazil. Normally, African countries are lacking with water resources and rainfall. In this situation, if the fresh water is used further for irrigation and cultivation of sisal plants, water resources will deplete in Tanzania. Because of this, Tanzania will have huge depletion of fresh water (Fig. 8(b)). Generally, the wastage of Non-Renewable Energy (NRE) is caused by the fiber processing (i.e. decortication, scrubbing and treatments). In Brazil, the NRE wastage is reduced due to the suitable practices and fiber treatments when compared to Tanzania (Fig. 8(c)). Majority of the sisal residues are used as biomass. The biomass is the excellent Renewable Energy (RE) resource which is used as various forms of energy. The sisal residues are used as RE almost equally for both countries (Fig. 8(d)). The Greenhouse Gas (GHG) can be calculated in terms of weight of the CO₂ equivalent emission. The GHG mainly influencing the global warming leads to the drastic climate change. It is found that the emission of GHG in Tanzania is three times higher than Brazil (Fig. 8(e)). This reveals that Tanzania does not properly maintain the residue disposal patterns.

Conclusion

It is concluded that the usage of sisal fiber reinforced composites have increased more than 30% in the past 25 years because of their economic and environmental benefits. This study on life cycle assessment of the sisal fiber provides knowledge for selecting right methods, treatments and product for right applications. In current scenario, the sisal fiber based products also increased tremendously in various applications due to their unique properties.

In some developing countries, most of the researchers are giving more importance to the natural fiber reinforced composites since the natural fibers are having low cost, high specific strength with low density and sustainability. The real time applications of the sisal fiber based products are reasonably low because of their misunderstanding of the physical, chemical and mechanical behaviors due to the environmental effects. These behaviors are highly sensitive to the matrix types, fiber lengths and orientations, manufacturing methods, physical and chemical treatment methods and strain rate. Since the sisal fibers are having excellent mechanical and tribological properties, it plays a vital role in defence and automotive industries.

The future scopes of the sisal fiber are given below.

- To maintain the consistent properties of the sisal fiber, there is a necessity to examine and manipulate the properties of the sisal fiber because it is ultimately depending on the sources, processing and nature of the environment.
- The complete study of the sisal fiber will give the knowledge about the thermal and tribological properties. Based on this study, the applications of the sisal fiber can be extended.
- Since the sisal fibers are discontinuous and have rough surface, the twist is mandatory for making the products such as ropes, fabrics and mattresses. In order to increase the natural fiber products, still there is adequate research required on the proper twisting and non-twisting of the sisal fiber.
- The researchers are promoting the usage of the biodegradable and eco-friendly fibers. In the same way, there is a research gap in the recyclability and repeatability of the sisal fiber products and their composites.
- The cradle to gate LCA analysis on sisal fiber gives the complete information about the environmental impacts of the sisal fiber from initial stage to the product stage.

Introduction

Our society are increasingly demanding products made from renewable and sustainable resources that are biodegradable, non-petroleum based and have low environmental, animal/human health and safety risks. There is a growing trend to use bio-fibers as fillers and/or reinforces in plastics composites ([Abdul Khalil *et al.*, 2012](#); [Jawaid and Abdul Khalil, 2011](#); [Abdul Khalil *et al.*, 2014](#); [Abdul Khalil *et al.*, 2016b](#); [Fatah *et al.*, 2014](#); [Abdul Khalil *et al.*, 2016a](#); [Abdul Khalil *et al.*, 2017](#)). In recent years, there is increasing interest in the development of biodegradable and/or plant derived composite materials which sometimes referred to as “green composites because of the strong global demand for creating renewable sources. In this context, cellulose and its nanostructures have gained considerable interest among the scientific community due to its inherent fascinating properties like high specific surface area, aspect ratio, mechanical properties etc., ([Gopakumar *et al.*, 2017](#)). Cellulose is a homo polysaccharide consisting of a linear chain of linked anhydroglucose units. The three hydroxyl groups on each anhydroglucose units enable the cellulose chains to assemble with each other. Nanocellulose in the form of cellulose nanocrystals and cellulose nanofibers has been the focus of a significant research interest during the last two decades. Nanocellulose is an abundant and renewable nanomaterial flexibility with chemical inertness and possibility to modify the surface chemistry. Now a days, the innovative nanocellulose aerogels have gained substantial attention in the scientific community due to their renewability, good mechanical properties, low density, high porosity, natural biodegradability, and environmental friendliness [Lavoine and Bergström \(2017\)](#). These attractive properties facilitate the use of nanocellulose aerogels in various environmental and engineering applications. This article reviews recent advancement of nanocellulose aerogels and discusses about its possibility for sustainable future materials. These materials can be applied for environmentally friendly engineering composites that surpass current technological limits of composite materials.

Extraction of Cellulose Nanofibers (CNfs) and Cellulose Nanocrystals (CNCs)

Mainly nanocelluloses are classified into (1) cellulose nanofibers (CNFs) (2) cellulose nanocrystals (CNCs) and (3) bacterial nanocellulose (BNC). The CNCs have nano dimension in both length and diameter wise, whereas CNFs have length in micro dimension and diameter is in the nano dimension is shown in [Fig. 1](#). Isolation of nanocellulose from renewable source is becoming an important area for the researchers all over the world. A lot of procedures have been reported for the extraction of CNFs from the plant cell wall. There are several mechanical treatments have been used to extract CNFs from various sources. These processes mainly include high pressure homogenization, grinding, cryocrushing and high intensity ultrasonic treatments which led to the transverse cleavage of the cellulose fibers.

Chen *et al.* reported a method to fibrillate the raw dried cotton fibers into individual cellulose nanofibers by chemical purification and pre-treatment by a high-speed blender combined with high pressure homogenization ([Chen *et al.*, 2014](#)). Abe *et al.* obtained CNFs with a uniform width of 15 nm from wood by the grinding treatment in an undried state ([Abe *et al.*, 2007](#)). Cryocrushing combined with a high-pressure fibrillation process was used by Wang & Sain for the isolation of CNFs with diameters in the range of 50–100 nm from soyabean stock ([Wang and Sain, 2007](#)). CNFs were individualized from poplar wood by explosive chemical pre-treatment and high-intensity ultrasonic treatment by Chen *et al.* When the output power of ultrasonic treatment was greater than 1000 W, CNFs were 5–20 nm in width and several microns in length were obtained ([Chen *et al.*, 2014](#)). Deepa *et al.* reported the extraction of CNFs from the banana plant by the steam explosion process in an autoclave ([Deepa *et al.*, 2011](#)). Cellulose acetate (CA) nanofibers with fiber diameter ranging from 200 nm to 1 μ m using electrospinning technique was reported by Ramakrishna *et al.* and the solvent employed was acetone/DMF/Trifluoroethylene (3:1:1) mixture ([Ma *et al.*, 2005](#)). Tibolla *et al.* isolated CNFs from banana peel bran using chemical treatment and enzymatic treatment (alkaline treatment and hydrolysis with xylanase). Nanofibers produced from enzymatic treatment had an average diameter of 7.6 nm and length in the range of 2889.7 nm ([Tibolla *et al.*, 2017](#)).

CNCs are typically prepared by acid hydrolysis of the cellulose nanofibers shown in [Fig. 2](#). The amorphous portion in the cellulose microfibrils could be hydrolysed by the strong acid treatment and resulting a rod like crystalline structures are known as cellulose nanocrystals (CNCs) or whiskers. Several types of acids have been employed for the acid hydrolysis of cellulose microfibrils that includes sulphuric acid, hydrochloric acid, oxalic acid, hydrobromic acid (HBr) and nitric acid

Fig. 1 Schematic representation of nanocelluloses obtained from wood cellulose fibers. The cellulose fibers are first deconstructed into microfibrils and after various processing steps into cellulose nanofibrils (CNF). Cellulose nanocrystals (CNCs) can be further obtained by using acid hydrolysis. Reproduced from Rajala, S., Siponkoski, T., Sarlin, E., *et al.*, 2016. Materials chemistry and the futurist eco-friendly applications of nanocellulose: Status and prospect. J. Saudi Chem. Soc. 22, 949–978. doi:10.1016/j.jscs.2018.02.005. Reproduced with permission from Elsevier Ltd.

(Maiti *et al.*, 2013; Sonia *et al.*, 2013) Among the acid hydrolysis treatments, sulphuric acid treatment of cellulosic material has been widely used to extract CNCs. Recently Danial *et al.* extracted the CNCs from waste paper by acid hydrolysis using 60% (V/V) sulphuric acid solution at 45°C with constant stirring. They obtained the CNCs with length ranged in 100–300 nm (Danial *et al.*, 2015).

Extraction processes of nanocellulose plays an important role to tune the surface chemistries of nanocellulose and in turn for enhancing the adsorption efficiency towards various viruses in the water via electrostatic attraction. Tempo mediated oxidation is another method of extraction of cellulose nanofibers, where the 2,2,6,6-tetra methyl piperidine – 1-oxyl radical (TEMPO)-mediated oxidation of celluloses for regioselective conversion of the primary hydroxyl groups to carboxylate ones. In Tempo mediated oxidation the significant amounts of carboxylate and aldehyde groups were introduced into the native cellulose fibers,

maintaining their fibrous morphologies and crystallinity (Saito *et al.*, 2007). Ma *et al.* removed the virus from aqueous solution using Tempo oxidized cellulose nanofibers. From the TEMPO/NaBr/NaClO treatment, C6 positioned hydroxyl groups of cellulose molecules were partially oxidized into carboxylate/aldehyde groups, resulted in coverage of a negatively charged surface, which was effectively adsorbed positively charged virus via electrostatic attraction (Ma *et al.*, 2011). In summary it has been showed that by changing the surface charge densities of cellulose nanofibers by different extraction process, could possible to remove various pollutants in water via electrostatic attraction.

Nanocellulose Based Aerogels and its Applications

Aerogels are ultra-light weight materials with exceptionally high porosity within their network structure. Aerogels were first reported by Kistler (1931). They prepared aerogels by subjecting a wet gel precursor to Critical Point Drying (CPD) or lyophilization (freeze drying) to remove the solvent. They had been pursued for a multitude of applications due to their combination of feasible properties such as extremely low density, low mean free path of diffusion, high specific surface area, low dielectric constant and slow speed of sound. However, their inherent fragility limited their use in various fields where mechanical robustness is needed.

The nanocellulose aerogels can be fabricated via three steps: Dissolving/dispersing cellulose or cellulose derivatives, forming cellulose gel by the sol-gel process, and drying cellulose gel while basically retaining its 3D porous structure (Moon *et al.*, 2011). Nano cellulose aerogels could be prepared by dispersing nano cellulose in water using ultrasonic or mechanical methods, followed by subsequent drying with or without solvent exchange. Pääkkö *et al.* demonstrated the formation of MFC aerogel formation using either rapid freeze drying and drying by vacuum freezing, followed by sublimation. The MFC aerogels exhibited high porosity, with nanoscale pores in sheets of agglomerated MFC and macroscale pores between the sheets. The densities ranged to 0.020 g cm^{-3} (Pääkkö *et al.*, 2008). Shamskar *et al.* obtained NCC aerogels from raw cotton and cotton stalks by freeze drying method (Rahbar Shamskar *et al.*, 2016). Jin *et al.* reported highly porous nano fibrillated cellulose aerogels, of density approximately 0.02 g cm^{-3} , by the dissolution of cellulose in aqueous calcium thiocyanate solution followed by regeneration and freeze drying. Jin *et al.* (2004) Hoepfner *et al.* reported the same dissolution method, however, super critical CO_2 drying was utilized, which lowered the density to 0.010 g cm^{-3} (Hoepfner *et al.*, 2008). Nano cellulose-based aerogels exhibits densities ranging from 1 to 200 Kg m^{-3} and their porosity can be higher than 99%. The thermal and mechanical properties of aerogels are much influenced by their pore size and morphology. The particle size and shape and interactions and their processing routes accounts for the porous architecture.

Nanocellulose Aerogel as Efficient Media for Water Purification

Water pollution has drawn much attention now-a-days because of its disastrous effect on the environment and ecosystem. Industrial wastewater often contains broad ranges of chemical pollutant species including heavy metal ions, such as Cr^{6+} , Pd^{2+} and Hg^{2+} , dyes, organic solvents, pesticides, herbicides and the like. Lack of proper treatment results in the leakage of chemical species into the groundwater, generating harmful diseases. Various techniques including chemical precipitation, biological treatment, membrane technology, electrolytic reduction, ion exchange and adsorption have been adopted to tackle this problem. Among these approaches, adsorption is the most convenient method. The emergence of nanocellulose as potential adsorbents for environmental remediation replaced the conventional waste water treatment technologies in an environment friendly manner. This method involves removal of chemical species from wastewater including heavy metal ions, pesticides, herbicides and dissolved organic pollutants. Owing to the large surface area and excellent adsorption capacities, nanocellulose, especially Cellulose nanofibers (CNFs), have been employed for the removal of pollutants from water (Mahfoudhi and Boufi, 2017).

Heavy metal removal

Kardam *et al.* prepared Cellulose nanocrystals (CNCs) from rice straw by acid hydrolysis to use them as adsorbents for Pb^{2+} , Ni^{2+} and Cd^{2+} . The adsorption capacities were relatively low reaching about 9.7 mg g^{-1} Cd^{2+} , 9.42 mg g^{-1} Pb^{2+} and 8.55 mg g^{-1} Ni^{2+} ions from 25 mg l^{-1} of metal solution (Kardam *et al.*, 2014). In addition, Yu *et al.* studied the effect of CNC modified with succinic anhydride on the adsorption properties of nanocellulose for Pb^{2+} and Cd^{2+} . Although CNCs demonstrated interesting capacities to adsorb heavy metal ions, their strong tendency to aggregate has seriously affected their practical applications in water treatment (Yu *et al.*, 2013).

Ion exchange and chemical complexation were the main two mechanisms evoked in heavy metal adsorption. The functional groups of the adsorbent surface in chemical complexation have site interactions with specific kinds of metal ions. For this reason, surface modification is necessary to increase or introduce ionizable, ionic or complexing sites on the surface of the nanocellulose on which the metal is adsorbed. Hokkanen *et al.* reported the removal of heavy metals by using amino modified nanostructured Microfibrillated nanocellulose aerogels. Carboxylic sulfate and amine were among the most prevalent groups generated to boost the adsorption capacity. They modified CNFs with 3-aminopropyltriethoxysilane (APS) which successfully adsorbed Ni^{2+} , Cu^{2+} and Cd^{2+} heavy metal ions from water (Hokkanen *et al.*, 2014).

Xu He *et al.* demonstrated for the first time, freeze dried and quaternary ammonium-functionalized aerogels from soft wood CNFs, as excellent candidates for the removal of heavy metal ion pollutants, such as those of Cr (VI) from water. The low density,

high porosity of aerogel together with its large specific surface area enabled fast and efficient removal of Cr(VI) from water. CNFs Quaternary ammonium-functionalized CNFs were prepared through a chemical reaction between CNFs and 2,3-epoxypropyl-trimethylammoniumchloride under an alkali environment. The aerogel was covalently crosslinked to stabilize the 3D structure. The aerogels retained a large specific surface area in combination with the unique porous structure leading to the rapid and efficient removal of Cr (VI) from water. With only 1 g of aerogel, more than 99% of Cr (VI) in 1 L of 1 mg/L solution could be removed in 50 min. Besides, the aerogel also exhibited excellent reusability with a decrease in the percentage adsorption from 90.9% to 84.9% (He *et al.*, 2014).

Removal of dyes

Synthetic dyes have a profound use in many large scale as well as small scale industries such as textile, paper, leather, food and cosmetic goods. Organic dye molecules chelate strongly to various metal ions which imparts toxicity to fish and other aquatic organisms. Furthermore, dyes in water bodies absorb light to impede light penetration and reduce photosynthetic activities where by inhibiting growth of aquatic flora. Dye removal from wastewater is achieved through adsorption, sedimentation, filtration, chemical coagulation, and oxidation or treatment with microorganisms. Malachite green (MG), an N-methylated diaminotriarylmethane, is a cationic dye, which has been widely used as a parasiticide, fungicide and antiprotozoan in aquaculture, medical disinfectant and anthelmintic. Accumulation of MG in living organisms can become cytotoxic, mutagenic, teratological and carcinogenic.

Jiang *et al.* fabricated an ultralight weight aerogel from TEMPO oxidized CNFs via a three-step freezing-thawing induced hydrogel formation, tert-butanol exchange and freeze-drying to a honeycomb cellular structure consisting of a few hundred μm wide irregularly shaped open cells surrounded by mesoporous (8–60 nm) thin walls of self-assembled CNFs. The macro- and meso-porous structure along with high specific surface (193 m^2/g) and negatively charged surface effected the removal of cationic dye. The MG adsorption on CNF aerogels exhibited a monolayer Langmuir adsorption isotherm with maximum adsorption of 212.7 mg/g, corresponding to participation of 46% of the total surface carboxyl's. The CNF aerogel showed over 92% MG removal efficiency in a single batch adsorption at 10:5 mg/mL aerogel/MG ratio and 100 mg/L dye concentration (Jiang *et al.*, 2017).

Removal of oil from water

Like other industrial wastes, oil leakage has also added much to the issue. Several physical, chemical and biological methods such as *in situ* burning, chemical treatments, bioremediation have been developed to tackle with this problem. Among these, physical absorption via absorbents is considered the most promising way as it is cost-effective and does not generate by products. For an effective sorption to occur, the sorbents should possess high sorption capacity and porosity, oil/water selectivity, and a fast sorption rate. Conventional oil and chemical sorbent materials can be grouped into three major classes: Inorganic mineral sorbents, synthetic polymer sorbents, and natural organic sorbents. Inorganic mineral sorbents and synthetic sorbents are highly oleophilic and hydrophobic. However, they degrade or disintegrate very slowly. Natural sorbents on the other hand, have moderate sorption capacity, comparable or sometimes lower density than inorganic and synthetic sorbents, and excellent biodegradability. Currently, research has been focused on developing novel, high quality materials with low density and high sorption capacity, that are bio-degradable and ecofriendly.

Nanocellulose aerogels as absorbents have attracted considerable research interests due to their high absorption capacities (more than 40 times by weight), environmental friendliness, biodegradability and sustainability. In addition, their high compression strength and high flexibility, which accounts for their reusability, also makes them suitable for absorption of oil and other organic pollutants. Yet, the inherent high hydrophilicity of the nanocellulose surface, reduces the oil/water selectivity and destroys the porous structure of the cellulose aerogels (Jin *et al.*, 2011). Hydrophobization of the nanocellulose surface is being done to address the above difficulty.

Korhonen *et al.* demonstrated such a material, based on functionalized cellulose nanofibrils, where cellulose is natural, renewable and the most abundant polymer. They prepared highly porous nanocellulose aerogels via vacuum freeze drying from microfibrillated cellulose hydrogels. They showed that by functionalizing the native cellulose nanofibrils of the aerogel with a hydrophobic titanium dioxide oleophilic coating to selectively absorb oils from water. Because of the low density and ability to absorb non-polar liquids and oils up to nearly all of its initial volume, the surface modified aerogels could remove organic contaminants from the water surface as shown in Fig. 3. They showed that the absorption was close to the overall volume of the aerogel (80%–90% vol/vol) and the mass-based adsorption capacity varies from 20 to 40 (wt/wt) depending on the density of the liquid. They concluded that the nano cellulose based aerogels will be a good promising candidate as oil absorbents for future sustainable applications (Korhonen *et al.*, 2011).

Another work was done by Jin *et al.* and they demonstrated the super hydrophobic and super oleophobic nanocellulose aerogels, consisting of fibrillar networks and aggregates with structures at different length scales, support considerable load on a water surface and on oils. They showed that the load carrying capacity of the aerogels might be a few orders of magnitude larger than the weight of the aerogel itself. They suggested that this would open up a new platform for carriers or for coatings that have large load bearing capability on various organic and aqueous liquids including oil-polluted water (Jin *et al.*, 2011). Another interesting work was done by Meng *et al.* and they reported a sponge-like nanocellulose-based carbon aerogels for oil absorption. They prepared carbon aerogel material via heat treatment of cellulose microfibril aerogel. They showed that this aerogel was useful as a highly porous oil absorbent (99% of porosity) with ultra-light density (0.01 g/cm^3), hydrophobic properties (144° static

Fig. 3 Oil spill removal from water. (a) Paraffin oil (colored for clarity) floating on water; (b) the oil being absorbed into the aerogel; and (c) all of the floating oil has been absorbed. (d) The oil-filled aerogel can be washed simply by immersing it in a solvent, such as ethanol. The oil gets removed as shown by the red streaks. Reproduced from Korhonen, J.T., Kettunen, M., Ras, R.H.A., Ikkala, O., 2011. Hydrophobic nanocellulose aerogels as floating, sustainable, reusable, and recyclable oil absorbents. *ACS Appl. Mater. Interfaces* 3, 1813–1816. doi:10.1021/am200475b. Reproduced with permission from American Chemical Society.

contact angle), fast absorption rate and multiple reusability as shown in the Fig. 4. Their investigations revealed that carbon aerogel which was heat treated at 700° C had higher oil absorption capacity of various types of oils. This was due to the fact that 3D-network structure formed by the entanglement of carbonized cellulose fibrils and the large surface energy of carbonized fibers. They concluded that the unique properties of carbon aerogel from nanocellulose, along with the advantages of using a natural renewable, low cost and sustainable material, recommend carbon aerogel for a wide range of oil-spill clean-up applications (Meng *et al.*, 2015).

Feng *et al.* reported about the advanced fabrication and oil absorption properties of super-hydrophilic recycled cellulose aerogels. They coated the recycled cellulose aerogels with methyl/trimethoxysilane (MTMS) via chemical vapour deposition yielded, a very stable super hydrophobicity for over five months and excellent oil absorption capacities upto 95 gg⁻¹ with the 0.25 wt% cellulose aerogel. It was shown that the initial cellulose fiber concentration significantly affects the oil absorption capability of the developed cellulose aerogels. They concluded that the demonstrated super-hydrophobic recycled cellulose aerogels could be one of the very promising sorbents for oil spill cleaning as shown in the Fig. 5 (Feng *et al.*, 2015).

Zhang *et al.* fabricated a highly efficient cellulose based aerogel with high mechanical strength via novel method. The prepared aerogel possessed perfect 3D skeleton and interconnected pores similar to the honey comb, exhibiting excellent oil/water selectivity. In addition, the demonstrated aerogels exhibited stable super hydrophobic and superoleophilic properties even towards a strong mechanical abrasion. Moreover, they showed that demonstrated cellulose aerogels can be reused up to 30 cycles (Zhang *et al.*, 2016). Wang *et al.* reported an ultra-weight; elastic, cost-effective, highly recyclable super absorbent from microfibrillated cellulose fibers for oil spillage cleanup. They demonstrated a simple method to produce a low cost highly recyclable super absorbent from renewable cellulose fibers via simple and environmentally friendly microfibrillation treatment and freeze drying. The demonstrated

hydrophobic superabsorbent could selectively absorb oil from an oil-water mixture and showed an ultra-high absorption capacity of 88–228 mg/g, which was comparable to those of other novel carbon-based super absorbents. More importantly, the superabsorbent showed excellent flexibility and could be repeatedly squeezed without structure failure (more than 30 times) (Wang *et al.*, 2015).

Nanocellulose Aerogels as Air Filters

Nano celluloses can be used as components in porous materials with large specific surface areas to create high performance products such as filters, adsorbents, catalyst supports, cell culture substrates, thermal insulators, and drug carriers (Metreveli *et al.*, 2014).

Fig. 6 Strategy for the preparation of TOCN aerogel. Reproduced from Nemoto, J., Saito, T., Isogai, A., 2015. Simple freeze-drying procedure for producing nanocellulose aerogel-containing, high-performance air filters. *ACS Appl. Mater. Interfaces* 7, 19809–19815. doi:10.1021/acsami.5b05841. Reproduced with permission from American Chemical Society.

Generally good air filters have high air permeability (i.e., low pressure drop), and large surface areas that can capture more particles (Podgórski *et al.*, 2006). Nano celluloses are a promising candidate for air filter applications due to its fibrous nature which reduce the resistance in filters and thereby enhance the frequency of collision of particles with the fibers (Mao *et al.*, 2008).

Nemoto *et al.* reported a (2,2,6,6-tetramethylpiperidine-1-oxyl) TEMPO oxidized nanocellulose aerogel for the high-performance air filtration application (Nemoto *et al.*, 2015). They prepare TEMPO oxidized aerogel freeze drying of the TEMPO-oxidized cellulose nanofibril (TOCN) dispersions with tert-butyl alcohol (TBA) mixture as shown in the Fig. 6. They observed that the TOCNs were homogeneously dispersed in the water/TBA mixtures at TBA concentrations up to 40% w/w. They found that when a commercially available, high-efficiency particulate air (HEPA) filter was combined with TOCN/water/TBA dispersions prepared using 30% TBA, and the product was freeze-dried, the resulting TOCN aerogel-containing filters showed superior filtration properties. They concluded that the enhanced filtration efficiency of the demonstrated TEMPO nanocellulose aerogels was due to its nanoscale, spider-web-like networks of the TOCNs with large specific surface areas as shown in the Fig. 7.

Another work was reported by Lu *et al.* and they fabricated a novel air filter with spider-web-like structure based on renewable and biodegradable fibrillated cellulose fibers. They demonstrated an effective strategy for network structure regulation during freeze-drying process. Their results showed that the air filter with spider-web-like structure, whose filtration efficiency for model PM particles with the diameter of 300 nm could exceed 99%, was obtained from a fibrillated cellulose fiber/water/Tert-Butyl Alcohol (TBA) mixture by freeze-drying. They concluded that the demonstrated work paved a way to fabricate high-performance air filters based on renewable materials (Lu *et al.*, 2018).

Nanocellulose Aerogel for Flame Retardant Applications

Cellulose aerogels are ultralight three-dimensional porous materials, which combine the excellent properties of highly porous aerogels such as high specific surface area, low density, low thermal conductivity, and high insulation, with the fantastic properties of sustainable biopolymers such as biodegradability and biocompatibility. Cellulose aerogel is considered one of the most promising heat insulating materials due to its abundant internal pores and good thermal insulation performance. However, nanocellulose aerogels are easy to ignite, which is the main limitation to its wide applicability in many commercial applications. In this context, the researches have been more focused to develop the flame retardant nanocellulose aerogels while maintaining their unique properties for varying technological application. He *et al.* reported a facile strategy to construct flame retardant, sound-adsorption and mechanical enhancement cellulose-based composite aerogels by the incorporation of aluminum hydroxide nanoparticles (AH NPs) into cellulose gels via an in-situ sol-gel process followed by freeze-drying to coat AH NPs on cellulose composite aerogels (AH NPs@cellulose composite aerogels) as shown in the Fig. 8.

The prepared composite cellulose aerogels showed excellent flame retardancy, the peak of heat release rate (PHRR) of the composite aerogels decreased significantly from 280 W/g of the control sample to 22 W/g, and total heat release (THR) of the composite aerogels decreased remarkably from 13.2 kJ/g to 1.6 kJ/g as shown in the Fig. 9.

Moreover, the incorporation of AH NPs composite aerogels exhibited remarkable mechanical properties, the compressive strength of the composite aerogels increased significantly from 0.08 to 1.5 MPa. In addition, AH NPs composite cellulose aerogels have excellent sound absorption at high frequencies with a maximum sound absorption coefficient of 1. In summary, they concluded that the demonstrated work was a facile strategy to rationally construct flame retardant, mechanically robust,

high-efficiency sound-adsorption and superamphiphobic cellulose-based composite aerogels, which have promising applications in the future as green engineering materials (He *et al.*, 2018).

Yuan *et al.* prepared cellulose-silica composite aerogels by in situ formation of silica nanoparticles via a two-step sol-gel process in cellulose gel, which was prepared by dissolving cotton pulp in 1-allyl-methylimidazole chloride ionic liquid (AmimCl) and then regenerating from AmimCl/water bath. The results showed that the composite aerogels displayed an enhanced transparency, compressive properties, and thermal and thermal-oxidative stability with increasing of silica content. They found that the incorporation of silica nanoparticles also improved the mesoporous characteristics of aerogels including specific surface area and mesopore volume, and significantly delayed the decomposition of cellulose, suppressed the heat release during combustion. The composite aerogels with high silica content (33.6% or more) exhibited good transparency with light transmittance as high as 78.4% at 800 nm, even higher than the neat cellulose aerogels, and presented excellent flame-retardant performance, achieving self-extinguishment after ignition. They conclude that the transparent cellulose-silica composite aerogels with enhanced

mechanical performance and improved flame retardancy might show great potential in a wide variety of applications (Yuan *et al.*, 2017).

Another interesting work was reported by Han *et al.* and they fabricated flame retardant cellulose aerogels from waste cotton fabrics by in situ synthesis of magnesium hydroxide nanoparticles (MH NPs) in cellulose gel nanostructures, followed by freeze-drying as shown in the Fig. 10. They also found that the three dimensionally nanoporous cellulose gel prepared from the NaOH/urea solution could serve as scaffold/template for the non-agglomerated growth of MH NPs (Han *et al.*, 2015).

Conclusion

Nanocellulose has gained considerable attention in last 10 years among the scientific community due to its fascinating properties and sustainable nature. Among the nanocellulose, cellulose nanofibers and cellulose nanocrystals has been becoming very popular due to its ease of preparation and fabrication methods. Cellulose aerogels are ultralight three-dimensional porous materials, with excellent properties like high specific surface area, low density, low thermal conductivity, and high insulation, with the fantastic properties of sustainable biopolymers such as biodegradability and biocompatibility. These properties make nanocellulose aerogel as efficient substrate for various engineering applications. Nanocellulose possesses a blend of properties suitable to produce ultralight, strong and flexible foams and aerogels for various technological applications. Numerous processing procedures have been established that enabled the production of nanocellulose-based foams and aerogels with a tunable porosity and pore architecture. The recent advances in nanotechnology have proved that, the research on nanocellulose-based foams and aerogels will be continued to grow. Future focus will be on designing of the novel methodologies to fabricate light weight materials with fascinating properties from nanocellulose for specific engineering applications

Introduction

Plastic waste is a growing concern in today's society, well-acknowledged by both government and private sectors. Waste disposal and recycling are simply not enough to manage completely the enormous volume of waste produced. Moreover, petroleum product demand is increasing while supply is uncertain.

The industrial sector has responded by looking for new material substitutes that reduce dependence on petroleum and fossil fuels (Salazar *et al.*, 2011; Faruk *et al.*, 2012; Al-Oqla and Sapuan, 2014). Natural fiber composites (NFCs) present an excellent solution to this problem. Composites are made from two or more constituent materials – matrix and reinforcement fiber – with significantly different physical or chemical properties to produce a new material, which has better properties than the individual components alone. NFCs consist of natural fiber reinforcement (made from fibers such as kenaf, flax, hemp, coir or cotton) incorporated into a (typically) polymer- or ceramic-based matrix (Taj *et al.*, 2007; Smitthipong *et al.*, 2013).

NFCs have become an exciting selection for the automotive industry because of their numerous advantages. Many researchers have demonstrated the mechanical, economic, and environmental benefits of NFCs (Mueller *et al.*, 2001; Kalia *et al.*, 2011; Savage and Evans, 2014; Mitschang and Hildebrandt, 2012). Natural fibers have been shown to enhance composite mechanical performance, reduce weight and processing time, decrease production cost, and improve passenger safety and shatterproof performance (Chen, 2005). They are also biodegradable, nonabrasive to processing equipment, and can be used as acoustic and thermal insulators (Alves *et al.*, 2010). Moreover, the combination of thermoplastic matrix and natural fiber can provide other desirable properties such as high resistance to adverse environmental conditions (moisture and UV radiation), as well as providing significant stiffness and hardness (Salasinska and Ryszkowska, 2012) and superior vibration damping characteristics. The latter is significant as the addition of damping materials to address noise, vibration and harshness is an increasing percentage of vehicle mass (National Research Council, 2011).

The aim of this article is to review the current state of NFC technology and its level of implementation in the automotive sector. In so doing, it is hoped that the work will stimulate innovation and development in these new environmentally responsible products while at the same time spur further adoption of the technology in the automotive industry.

Background

Natural Fiber Properties and Potential

Natural fibers are generally classified into two broad categories: wood fibers and nonwood fibers (see Fig. 1). The most extensively studied and used fibers in automotive applications are nonwood fibers, especially those collected from the bast of plants (e.g., flax, hemp, jute and kenaf) and from leaves (e.g., sisal and henequen) (Faruk *et al.*, 2014; Mohanty *et al.*, 2002). However, researchers and industry proponents have also given significant attention to seed fibers (e.g., cotton, coir and coconut) as well as straw and grass fibers (e.g., wheat straw, bagasse, and bamboo) as viable options for composites.

Natural fibers offer environmental, economic and technical advantages when compared to synthetic fibers. Table 1 summarizes general attributes of various bast, leaf and seed fibers, side-by-side with traditional reinforcement fibers, glass and carbon. In this broad comparison, plant fibers show advantages in terms of cost and density but they especially stand out in terms of environmental benefits. Unlike synthetic fibers, they are biodegradable, carbon sequestering, and cause no human health concern during production. Also, natural fibers are not just renewable, but rapidly renewable with some species capable of being harvested up to six times per year (Beda Ricklin, 2015). Indeed, sustainability is one of the main drivers behind the eco-car trend and as public awareness increases on the sustainable aspects of plant fibers, they will likely gain more attention for commercial use.

Generally, natural fibers have high aspect ratios while the structure of the fiber is hollow and laminated with molecular layers in an integrated matrix. This anatomical structure results in excellent technical capabilities with low density and consequently, high strength-to-weight ratios. The specific mechanical properties are comparable with that of glass fibers. Fig. 2 compiled from published values in the literature (Koronis *et al.*, 2013; Dittenber and Gangarao, 2012; Shah, 2013; Yan *et al.*, 2014; Dicker *et al.*, 2014; Zini and Scandola, 2011; Bismarck *et al.*, 2006) provides a visual comparison of the range and potential of specific stiffness and strength for many commercially used fibers. The comparison is favorable for several types of natural fibers. Most species have higher potential specific stiffness than glass and for many, the specific strength is quite comparable to glass. While the wide range of properties is relective of the well-known inherent material variability of natural fibers (ie, quality of fiber varies due to growing climate or processing methods), it is also partially due to differing conditions between studies, such as different fiber moisture content or test methods employed (Faruk *et al.*, 2014).

It is important to note that in order to improve the mechanical properties of the composite, modification of the natural fiber surface is necessary. Almost all natural fibers are hydrophilic and, generally, polymer matrixes are hydrophobic so the compatibility of the two materials is poor. Therefore, modification is an important step prior to mixing them. Commonly, research interests lay in modification

Table 2 Pros and cons of NFC in automotive applications

Pros	Cons
Low density and lightweight leading to the weight reduction of 10%–30% in comparable parts	Concerns over the unevenness of the fiber supply and long term availability of fiber
Sustainable and renewable resource	Could be more expensive if fully bio-based and biodegradable
Good mechanical and manufacturing properties	Extremely sensitive to moisture and temperature
Relatively good impact performance	Uncontrolled biodegradable can occur
Occupational health advantages in assembly and handling compared to glass fiber	High variability properties
Biodegradable (if proper matrix is used)	
Good thermal and acoustic insulation properties	
Relative cost advantages compared to conventional constructions	
Low energy consumption	

of the natural fiber more than in the polymer matrix. Modification depends on either chemical or physical techniques, mainly focused on grafting between the natural fibers and the matrix to improve interfacial interaction (La Mantia and Morreale, 2011). For example, coupling agents (trichloro-s-triazine and di-methylol melamine) can create covalent bonds between the cellulose and the polymer matrix (Zadorecki and Flodin, 1986), or chemical treatment with sodium hydroxide, isocyanate and peroxide can increase bonding between sisal and a PE matrix thereby enhancing mechanical properties of the composite (Joseph *et al.*, 1996).

It is speculated that the next generation composite will be a hybrid consisting of two or more fiber types in a polymer matrix (Sathishkumar *et al.*, 2014). Possible combinations of hybrid composites include natural/natural, natural/synthetic and synthetic/synthetic fibers. Hybrid composite materials have wide applications in the field of engineering due to low cost, strength-to-weight ratio and ease of manufacturing (Nunna *et al.*, 2012). They provide the possibility of achieving a blend of properties (such as stiffness, ductility and strength), which cannot be achieved by single fiber-reinforced composites. Hybrid composites also possess increased fatigue life, better fracture toughness and lower notch sensitivity compared to single fiber-reinforced composites. Research on various combinations of synthetic fiber-based hybrid composites revealed that they had certain advantages like high specific strength, high toughness, and high impact resistance (Shahzad, 2011).

Challenges of Using Natural Fibers

Although there are many positive aspects of using NFCs, there are also negative factors that prevent a more widespread adoption of the technology. Advantages and disadvantages are summarized in Table 2 (Fung and Hardcastle, 2001; Bledzki *et al.*, 2006). For example, sensitivity of the natural fiber to moisture and temperature currently restricts most NFC applications to interior parts (e.g., trim in dashboards, door panels, parcel shelves, seat cushions, backrests, and cabin lining).

It should also be noted that the challenges that NFCs have in becoming more broadly adopted by the automotive industry are in many ways representative of the challenges faced by composite materials in general, and are not exclusive to NFCs. For example, the BMW i3 and i8 are being touted as the first mass production automobiles based upon a composite architecture. Nonetheless, the increase of public awareness of environmental problems about what to do with nondegradable, nonrecyclable contents at

the end of product life is having an impact on the industry to favor switching from synthetics to natural fibers. To this end, the United States and Europe have both issued specific directives on end-of-life vehicles. The European Commission implemented a "European Guideline 2000/53/EG" that set a goal of improving automotive recyclability to 85% of a vehicle (by weight) being recyclable for 2005. This percentage will be increased to 95% by 2015 (European Parliament and Council of the European Union, 2000). Such legislation is a significant driving factor toward the adoption of NFCs. It also represents a broader accounting of the environmental and social cost of industrial production.

Commercial Implementation

Processing Techniques and Products

In general, production technologies for NFCs are similar to those for the production of glass fiber composites. During processing, temperatures must not exceed 200°C, and the time that the material is exposed to high temperature should not be too long, to avoid destruction of the fibers. Compression molding, injection molding, extrusion, thermoforming, resin transfer molding and sheet molding are common processes used to manufacture NFCs.

Table 3 presents some popular NFC products: their trade names, constituents, processes, and applications that are produced by automotive interior companies, Johnson Controls and FlexForm Technologies. The properties of these materials are summarized

Table 3 Commercial NFCs products and their respective constituents, fabrication process and applications

Product trade name	Fibers/polymer	Process	Automotive applications
Fibrit (in production since 1954)	Wood fiber (offcuts from sawmill processing)/acrylic resin	Wet forming process of wood fiber (94%)/acrylic resin mat Compression molded at 230–250°C	Carrier for covered door panels Covered or foamed instrument panels Covered inserts (currently in production for Mercedes-Benz, Opel)
Fibrowood (in production since 1998)	Wood fiber/acrylic resin, synthetic fiber	Preimpregnated needled wood fiber felt (wood fiber (70%) mixed with acrylic resin and synthetic fiber binder) Compression molded at 220°C	Carrier for covered door panels Covered or foamed instrument panels Covered inserts and components Covered seat back panels (currently in production for BMW, Ford, Mercedes-Benz, Opel, Hyundai)
PP-NF for injection molding	Fibrowood recycles/polypropylene granules, thermoplastic	Compounded shredded fibrowood recycles with PP → injection molding	Plastic retainer for seat back panel
Wood-stock (in production since 1982)	Wood flour/polypropylene or polyolefin	Extruded of thermoplastic sheet based on polyolefin and wood flour → the mat is heated in an infrared oven → compression molded in a low-temperature tool (coupling of the coverstock, additional inserts and cutting of holes as well as perimeter is carried out in a one-step process)	Carrier for covered door panels Carrier for armrest Carrier for covered inserts (currently in production for FIAT, Lancia, Alfa Romeo)
EcoCor (in production since 2000)	Bast fibers (flax, hemp, kenaf, etc.)/polypropylene	Bast fibers (50%)/PP fiber felt → heated to over 200°C → compression molded in a low-temperature tool (<40°C) → the coverstock can be applied in a one-step manufacturing process	Carrier for covered door panels Covered components for instrument panels Covered inserts Carrier for hard and soft armrests Seat back panels (currently in production for Dodge, Ford, Mercedes-Benz, Opel, Porsche, Volkswagen)
Natural mat with epoxy resin (NF-EP) (in production since 2003)	Natural fiber mat (flax or hemp)/epoxy resin	A natural fiber mat (flax or hemp) is imbued with epoxy resin (natural fiber content of NF-EP is 70%) → compression molded using a high-temperature tool (150°C) → the carrier can be laminated with TPO, textile or leather	Carrier for covered door panels (currently in production for BMW)
FlexForm	Bast fibers (flax, hemp, kenaf, jute and sisal)/polypropylene and polyester	50% bast fiber/50% PP non-woven mat → thermoformed at 200°C and 0.379 MPa using matched metal tooling	Door panels, door bolsters, headliners, side and back walls, seat backs, rear deck trays, pillars, center consoles, load floors, trunk trim (currently in production for Mercedes-Benz, Chrysler (DCX), Ford, GM, Honda, and Nissan)

in **Table 4** and some examples of these products are shown in **Fig. 3** (Bledzki *et al.*, 2006; Johnson Controls Inc., 2015; Promper, 2010; Flexform, 2015).

Applications

Automotive applications of NFCs can be traced as far back as the 1940s, when Henry Ford developed the first composite car using hemp fiber. The next occurrence was in the 1950s, with the production of the body of the East German Trabant. Other manufacturers followed suit Daimler-Benz (1994), Mercedes (1996), but NFCs only really began to play an important role in the

Table 4 Physical and mechanical properties of commercial NFC products

Trade name	Density (g/cm ³)	Flexural strength (MPa)	Flexural modulus (MPa)	Impact strength (kJ/mm ²)
Fibrit	0.75–0.80	30–45	3000–3300	20–30
Fibrowood	0.85–0.95	50–60	3000–3800	12–20
PP-NF	1.14	57	3800	12
Wood-stock	1.1	40	18	–
EcoCor	0.7–1.0	45–55	2300–2700	25–35
NF-EP	0.75–0.85	55–70	4500–5800	25–35
FlexForm	0.9	21–67	1793–3792	–

Fig. 3 Interior applications of natural fiber composites products by FlexForm Technologies (above) and Johnson Controls (below).

Table 5 Natural fiber composites applications by manufacturer

Manufacturer	Automotive parts	Car models
Audi	Seat back, hat rack, boot lining, spare tire lining, side and back door panel/flax, sisal	A2, A3, A4, A4 Avant, A6, A8, Roadstar, Coupe
BMW	Door panels, headliner panel, boot lining, seat back/sisal	3, 5 and 7 series and others
Citroen	Interior door panel/flax, jute	C5
Daimler-Chrysler	Windshield/dashboard, door panels, business table, pillar cover panel; A class, Travego bus: exterior under body protection trim; M class: Instrumental panel; S class: 27 parts manufactured from natural fibers/sisal, flax, coir, hemp, cotton	A, C, E and S class, Travego bus, Sebring convertible, Stratus
Dodge	Door panels, center console	Viper
Fiat	Door panels	Alfa Romeo 159
Ford	B-pillar, boot liner, door panels, seat backs/kenaf	Mondeo CD 162, D219, Focus, Freestar, all-new Ford Escape, Expedition
General motors	Cargo area floor, seat backs, tire cover, package trays, door panels/hemp, kenaf, flax	Chevrolet TrailBlazer, Cadillac DeVille, Daewoo Lacetti, Regal, Grand Prix, Monte Carlo
Honda	Cargo area	Pilot
Lotus	Interior carpets, body panels, seats, spoiler/hemp	Eco Elise (July 2008)
Mercedes-Benz	Door panels (flax/sisal/wood fibers with epoxy resin/UP matrix), seat backrest panel (cotton fiber), glove box (cotton fibers/wood molded, flax/sisal), instrument panel support, seat surface/backrest (coconut fiber/natural rubber), insulation (cotton fiber), molding rod/apertures, trunk panel (cotton with PP/PET fibers)	C, S, E, and A classes, 2004 Mercedes 164/251
Mercury	Door inserts	Cougar
Mitsubishi	Colt: instrumental panel; space star: door panels	Space star, Colt
Nissan	Trunk divider/flax	Sentra
Peugeot	Front and rear door panel	406
Opel	Instrumental panel, door panels, pillar cover panel, headliner panel	Zafira, Vectra, Astra
Renault	Rear parcel shelf	Clio, Twingo
Rover	Rear storage shelf or panel, insulation	Rover 2000 and others
Saab	Door panels	–
Saturn	Door panels, package trays	L300, LS
SEAT	Door panels, seat back	–
Toyota	Raum: cargo area floor, door panels, instrumental panel; ES3: pillar garnish and other interior parts/kenaf	Raum, ES3,
Volkswagen	Door panel, seat back, boot lid finish panel, boot line	Golf A4, Passat Variant, Bora
Volvo	Cargo floor tray, seat padding, natural foams	C70, V70

automotive industry in 1999, when Morassi produced seats made of coir with latex for trucks and top-of-the-line cars for Mercedes-Benz. Today, all of the major car manufacturers, including Daimler-Chrysler, Mercedes, Volkswagen, Audi Group, BMW, Ford, Opel, Toyota, Nissan, and Mitsubishi, use NFCs in various applications as summarized in [Table 5](#) ([Bledzki et al., 2006](#); [Dai and Fan, 2014](#); [Huda et al., 2008](#)).

NFCs are used mostly for interior parts such as dashboards, door panels, parcel shelves, seat cushions, backrests and cabin linings ([Bledzki et al., 2006](#); [Huda et al., 2008](#)). So far, there are only a few examples of exterior parts made from NFCs due to their high moisture absorption behavior: an example is the exterior under floor paneling on the Mercedes A-class made with abaca fiber-reinforced composite and other nonspecific exterior parts for Travego and Top Class models by Mercedes-Benz used flax fibers.

Automotive applications of NFCs have proven themselves very well, especially in the German automotive industries. Germany holds a dominant market position in terms of product innovation, research, and commercially available products; laying claim to two-thirds of all plant fibers consumed in the European automotive industry. In Germany, car manufacturers are aiming to make every component of their vehicles either recyclable or biodegradable ([Bruijn, 2015](#)).

In 2013, the nova-Institute (Germany) in cooperation with Asta Eder Composites Consulting (Austria/Finland) conducted a market study about biocomposites produced in the European Union (EU) ([Carus et al., 2013](#)). The report showed that the total volume of biocomposites, including wood and other NFCs, produced in the EU in 2012 was 352,000 t. Wood–plastic composites accounted for 260,000 t while the remaining amount represented other NFCs. Wood–plastic composite production for decking (174,000 t) and automotive (60,000 t) are the most important application sectors, followed by siding and fencing (16,000 t). Only the automotive sector was relevant for other natural (nonwood) fiber composites (90,000 t).

In the automotive sector, NFCs have a clear focus on interior trims for high value doors and dashboards. Wood–plastic composites are mainly used for rear shelves and trims for trunks and spare wheels, as well as in interior trims for doors. The total volume of wood and natural fibers used in the production of biocomposites for passenger cars and lorries produced in Europe in 2012 was 80,000 t ([Fig. 4](#)). Recycled cotton fiber composites were mainly used for the driver cabins of the lorries.

Fig. 4 Use of wood and natural fibers for composites in the EU automotive industry in 2012.

Future Directions and Challenges

While the share of biocomposites in today's total composite market in the EU (including glass, carbon, wood and natural fiber composite) is already an impressive 15%, even higher shares are expected in the future. NFCs are starting to enter other markets such as consumer goods, although they are still at a very early stage. In the EU, the production and use of 150,000 t biocomposites (using 80,000 t of wood and natural fibers) in the automotive sector in 2012 could expand to over 600,000 t of biocomposites in 2020, using 150,000 t of wood and natural fibers each along with some recycled cotton. Yet this fast development will not take place if there are no major political incentives to increase the bio-based share of the materials used in cars.

Besides the EU, according to a Food and Agricultural Organization survey, Tanzania and Brazil produce the largest amount of sisal. Henequen is grown in Mexico. Abaca is grown mainly in the Philippines. The largest producers of jute are India, China and Bangladesh. Presently, the annual production of natural fibers in India is about six million tons as compared to worldwide production of about 25 million tons. In temperate climate countries, flax and hemp are the most representative plants. Cultivation of kenaf has recently been introduced in several countries, and is now grown in places such as the United States, Malaysia, Bangladesh, Thailand, among others (FAO, 2012).

Since 2009, improved compression molding technology has shown impressive weight reduction characteristics of auto parts based on NFCs. Currently, it is possible to get area weight down to 1500 g/m² (with thermoplastics) or even 1000 g/m² (with thermosets), which are outstanding properties when compared to pure plastics or glass fiber composites. In addition, in 2012, three big paper companies in Europe and the United States recently introduced cellulose-based PP granulates for injected molded parts to the automotive market. The cellulose-based PP granulates have fiber shares of between 20 and 50% for new and interesting applications such as furniture, consumer goods and automotive parts. This technology is still small in volume but strong in innovation (Carus *et al.*, 2013). Recently, Johnson Controls developed a "visible natural fiber surface material" concept used for the instrument panel and door panels of the Johnson Controls re3 interior demonstrator (Johnson Controls Inc., 2015). This innovation enables a unique eco-fashion vehicle interior that shows natural wood fibers as a structural, visible surface material.

Today, many studies focus on the development of fully biodegradable green composites – those made from natural fibers and bio-based resins derived from soybeans, pure cellulose acetate, citrate-based plasticizer, and polylactic acid (PLA), for example. It is expected that the future will see increased use of these green composites due to their renewable and environmentally benign constituents (Bogoeva-Gaceva *et al.*, 2007). Research suggests that these are producible with competitive properties (Schuster *et al.*, 2014; Liu *et al.*, 2007).

Toyota has, in fact, begun producing Eco Plastic such PLA, Bio-PET, which is used for automotive applications (Boshoku, 2014). They substituted the PP used in the kenaf-based material with PLA resin and developed spare tire covers and door trim using 100% plant-derived kenaf-PLA that is more environmentally friendly. In 2011, Bio-PET derived from sugar cane and new ecological plastic were used in the CT200h and SAI, respectively. In cooperation with the Aichi Industrial Technology Institute,

Mitsubishi Motors developed an automotive interior material that uses a novel plant-based resin polybutylene succinate (PBS), combined with bamboo fiber for reinforcement. Parts made from the material was used in the interior of a revolutionary minicar launched in Japan in 2007 (Mitsubishi, 2006). Recently, Mitsubishi filed the patent about the method of producing automobile interior boards based on green composites. The composite material is comprised of bamboo, cotton, hemp and a mixture of cotton and hemp in decreasing order of content together with a biodegradable resin (PBS) (Terasawa *et al.*, 2009).

Conclusions

NFCs have good potential for both interior and exterior automotive applications. Their advantages include having low density and cost, high specific strength, and being sustainable and environmentally friendly. The resulting products from those composites can be both reused and incinerated and do not have to be land filled as glass fiber compounds, which can help in developing cars according to the EU end-of-life directive. Consequently, these composites are becoming attractive alternatives to glass and carbon fiber-reinforced polymer composites for automotive components; however, further research is necessary to overcome challenges such as moisture absorption, to instead enhance mechanical properties for use as exterior parts. In addition, the current intensive development of bio-based resin could provide fully bio-based composite options to future automotive designers. Market developments of NFCs also depend on the political framework: any political incentives for the use of natural fibers in the automotive industry could help increase existing volumes of natural fibers used. The future looks very bright for NFCs; in addition to the automotive industry, other markets, such as consumer goods and furniture, are beginning to incorporate NFCs into their products.

Introduction

Over a half century, the burden of human activities, especially economic ones, on the environment has dramatically exceeded regenerative and absorptive capacity of the biosphere and environmental degradations have become socio-ecological crisis that is firstly remarked by [Craig \(2016\)](#). Although many scholars and international organizations have tried to take attention to this deterioration and its detrimental impacts on the life for so long, policy makers have lately recognized that traditional economic development policies are not sustainable, and sustainability has been crucial to survive in development strategies. The definition of sustainable development, as is given in the Brundtland Report (1987), is “to meet the needs of the present without compromising the ability of future generations to meet their own needs”. Therefore sustainable development path consists of interconnected and interrelated systems in which the intergenerational/overlapping generational welfare is optimized ([Bhinge et al., 2015](#); [Kannegiesser and Günther, 2014](#)). Three dimensions must be followed closely in this course ([Basiago, 1998](#); [Stoddart, 2011](#); [Emas, 2015](#)). (i) *The Economic Dimension* (Economic Sustainability) in which human well-being is treated economically in terms of various conditions and indicators, (ii) *The Environmental Dimension* (Environmental Sustainability) considering health, depletion of natural resources, quality environment, and, biodiversity, and, (iii) *Social Dimension* (Socio-Sustainability) paying attention to human capital, cultural capital, social reconciliation and peace, the existence of socio-political institutions, equality, and, justice eventually.

In recent times, the increasing negative impacts of global warming and/or climate change have shown that environmental dimension is much more important for a thriving future. It is crucial to state that environmental sustainability is also a prior condition to be able to manage economic and social sustainable policy implementations ([Pearce and Barbier, 2000](#)). In this respect, environmental sustainability has become an important research topic from various perspectives.

These perspectives mainly consider (i) observing management side of sustainable development ([Durach and Wiengarten, 2017](#); [García-Onetti et al., 2018](#); [Virapongse et al., 2016](#); [Mikulčić et al., 2017](#)), (ii) designing environmentally sustainable products ([Diego-Mas et al., 2016](#); [Delmas and Burbano, 2011](#); [He and Gu, 2016](#); [He et al., 2017](#)), (iii) focusing on environmental awareness ([Iosifidi, 2016](#); [Deniz, 2016](#); [Simsekli, 2015](#); [Mei et al., 2016](#)), (iv) investigating whether renewable material usage contributes to reduce environmental pollution ([Bilgili et al., 2017](#); [Choudhury, 2016](#); [López and Yoon, 2016](#); [Dogan and Inglesi-Lotz, 2017](#)), and, (v) attempting to develop an indicator or index ([Faulkner and Fazleen, 2014](#); [Butnariu and Avasilcai, 2015](#); [Moria and Christodoulou, 2012](#); [Esty et al., 2005](#); [Wackernagel and Rees, 1996](#)) to monitor environmental sustainability by combining many environmental metrics at plant or country level.

In empirical analyses, researchers in general need to employ an environmental indicator or an index within their relevant models to observe environmental changes ([Brambila and Flombaum, 2017](#); [Dong and Hauschild, 2017](#)).

One of those indicators developed by [Wackernagel and Rees \(1996\)](#) which can observe environmental changes is ecological footprint (EF hereafter). The EF indicator refers to how much of environment is demanded by people ([Wackernagel, 2002](#)) and how much the regenerative biological capacity of the planet is demanded by human activities ([Kitzes and Wackernagel, 2009](#)). Thereby, EF has been widely accepted in the environmental literature as an important sustainability indicator ([Gu et al., 2015](#); [Wiedmann and Barrett, 2010](#); [Collins et al., 2018](#); [Zhang et al., 2017](#); [Ulucak and Lin, 2017](#)). This indicator, then, has become one of the most prominent indicators throughout theoretical and empirical researches of environmental issues in recent years ([Ding and Banihashemi, 2017](#); [Zhang et al., 2017](#); [Wang et al., 2018](#); [Li et al., 2017](#); [Gu et al., 2015](#); [Bartelmus, 2008](#); [Lu and Chen, 2017](#); [Chakraborty, 2018](#); [Rashid et al., 2018](#); [Ulucak and Apergis, 2017](#)). Additionally, The European Environment Agency (EEA, 2010, 2015) the European Parliament, the European Commission ([Best et al., 2008](#)), and the United Nations Development Program (UNDP, 2014) consider the EF a useful tool for measuring environmental performance since it provides a framework of setting goals, identifying options for action, and tracking progress toward stated goals ([Borucke et al., 2013](#)).

The EF consists of six elements (cropland footprint, carbon footprint, grazing land footprint, built-up land footprint, fishing grounds footprint, forest footprint). When these elements are examined, one may indicate that the carbon footprint caused by fossil energy sources has the largest share in increasing ecological footprints (see “Relevant Website section”). Therefore, renewable material usage will contribute to the sustainability by reducing carbon footprint. Due to technical and economic feasibilities, biomass can be an efficient tool for environmental sustainability as well as sustainable development ([Bilgili et al., 2017](#); [Bilgili and Ozturk, 2015](#); [Ozturk and Bilgili, 2015](#)).

Accordingly, this paper aims at investigating the effect of biomass usage on sustainable development by observing the potential impact of biomass consumption on EF and Greenhouse Gas Emissions (GHG). This paper also examines the interaction of EF and GHG variables to observe their roles in environmental degradation.

Eventually, this paper is expected to provide researchers and policy makers with possible energy policies to mitigate the negative impact of global warming in the World for environmental sustainability. Remaining of the study is organized as follows: Section “Environmental Sustainability and Sustainability Indicators” explains environmental sustainability and its indicators, Section “Literature Review” follows relevant empirical literature, Section “Data, Model and Methodologies” presents the data, model and methodologies, Section “Estimation Output” reveals empirical results, and, Conclusion section yields the highlights of this research.

Environmental Sustainability and Sustainability Indicators

Although sustainable development has economic, social and environmental dimensions, the environmental dimension needs to be given more priority since the origin of the sustainability issue mainly stems from rising environmental problems (Kidd, 1992; Dong and Hauschild, 2017; Goodland, 1995). Additionally, the aim of protecting the environment might improve the human welfare by providing societies with numerous materials for economic activities and by preventing human from environmental harms (Goodland, 1995).

This point of view has emerged a new paradigm called ‘ecological economics’ based on the framework of “limits to growth (Olafsson *et al.*, 2014). Holdren *et al.* (1995) underlined the requirements for environmental sustainability, and, they remarked “maintenance of essential ecological processes and life-support systems; preservation of genetic diversity; and sustainable utilization of species and resources” (p. 7). To be able to stay within these sustainable environmental frontiers (i) renewable resources should be used at a rate which do not exceed regeneration rates, (ii) nonrenewable resources usage should be less than development of alternative substitutes, and, (iii) pollution level should be within the absorptive capacity of the environment (Daly, 1991). These three items stated by Daly (1991) are underlined also by Organization For Economic Co-Operation and Development. OECD (2001) classifies the relevant items into three principles; *regeneration*, *substitutability*, and *assimilation*. Besides, OECD introduces a fourth principle, *avoiding irreversibility* principle, implying that irreversible adverse effects of human activities on the environment should be avoided. These principles are proposed to design policies for environmental sustainability. However, relevant environmental indicators are required to monitor and assess the aims and success of policies towards sustainability and to know whether things are getting better or worse (Dong and Hauschild, 2017). To this end, several environmental sustainability indicators are proposed by international organizations and/or non-governmental organizations. These indicators are *Key and Core Environmental Indicators* by OECD, *Convention on Biological Diversity Framework Indicators* by United Nations Environmental Programme (UNEP), *Sustainable European Biodiversity Indicators* by European Union European Environment Agency (EEA), *Environmental Performance Index (EPI)* by Yale and Columbia Universities, *Environmental Vulnerability Index* by Secretariat of the Pacific Community, *Living Planet Index* by World Wildlife Fund, *Happy Planet Index* by New Economics Foundation and *Ecological Footprint (EF)* by Global Footprint Network, respectively.

Among others, EPI and EF have become more prominent indicators in terms of their more comprehensiveness (Moria and Christodoulou, 2012; Wilson *et al.*, 2007; Olafsson *et al.*, 2014; Strezov *et al.*, 2017). At this juncture, sustainability issue in its entirety is discussed in two forms based on substitutability of capitals. Accordingly, capital is considered as the sum of natural capital that represents nature resources and man-made capital. Strong sustainability argues that natural capital and man-made capital cannot be substituted by following irreversibility principle, while weak sustainability states that decrease in natural capital can be compensated by increase in man-made capital (Pearce and Barbier, 2000). Hence, EPI and EF have stood out as an environmental sustainability indicator (Wilson *et al.*, 2007; Moria and Christodoulou, 2012; Strezov *et al.*, 2017).

EPI has been calculated by Yale and Columbia universities and biennially published since 2006. it includes nine issue areas (climate & energy, biodiversity & habitat, fisheries, forests, agriculture, water resources, water & sanitation, air quality, health impacts) focusing on ecosystem vitality and environmental health to score country performance (Hsu *et al.*, 2016; Emerson *et al.*, 2010; Esty *et al.*, 2008). Countries are ranked till 100 as 100 denotes best performance in the method of EPI aggregation and their performance may change over time. One may visit at website provided in “Relevant Websites section” address to have more details on the EPI’s calculation methods. The countries’ EPI scores of 2006, 2008, 2010, 2012, 2014 and 2016 have been calculated and published so far. One of the main objectives of EPI is to provide empirical data for long term analyses and to facilitate analytical assessments (Haberland, 2008). However, current available time dimension of EPI may not be sufficient in order to make long term analyses and policy implications. In this respect, EF may be an alternative sustainability indicator that enables long term analyses to investigate stochastic properties of environmental performance since it has annual data spanning from 1961 to 2013 and it is widely preferred for econometric analyses in the literature. Therefore, this study focuses on EF as environmental sustainability indicator.

EF developed by Wackernagel and Rees (1996) aims at observing the fact that how much the regenerative biological capacity of the planet is demanded by human activities. These activities are basically consumption and production of goods and services (Kitzes and Wackernagel, 2009). The biologically productive areas are considered in EF computations and the cropland, forest, and fishing grounds are included into calculations while deserts, glaciers, and the open oceans are excluded. In these frontiers, EF is an aggregation of six components: *cropland footprint*, *grazing land footprint*, *fishing grounds footprint*, *forest land footprint*, *built-up land footprint*, and, *carbon footprint*. *Cropland footprint* computes the area required to grow all crop products, including livestock feeds, fish meals, oil, crops and rubber. *Grazing land footprint* estimates the area of grassland used in addition to crop feeds to support livestock. *Fishing grounds footprint* quantifies the annual primary production required to sustain a harvested aquatic species. *Forest land footprint* measures the annual harvests of fuelwood and timber to supply forest products. *Built-up land footprint* takes into account of the area of land covered by human infrastructure: transportation, housing, industrial structures and reservoirs for hydroelectric power generation and *carbon footprint* represents the forest lands required for anthropogenic CO₂ absorption (Ewing *et al.*, 2010). Combining these six components, EF answers how much nature countries/regions have and how much they use it in terms of biologically productive areas. Biocapacity (BC), on the other hand, represents biologically productive areas of countries to be able to reproduce all resources demanded from nature.

EF accounts and calculations at country level are undertaken by Global Footprint Network (GFN) and these calculations for each country are released under the name of National Footprint Accounts (NFA). Several statistical databases, i.e., International Energy Agency (IEA), International Panel on Climate Change (IPCC) database, United Nations (UN) commodity trade statistics Database, Food and Agricultural Organization (FAO) production database, FAO trade database, FAO technical conversion factors, FAO fisheries statistical database, FAO ForeSTAT statistical database, Global Forest Resources Assessment, Global Agro-Ecological Zones (GAEZ), FAO ResourceSTAT statistical database, and, Global Land Use Database might be followed in NFA calculations.

Latest two versions of NFA calculations are explained in detail by Lin *et al.* (2016) and Lazarus *et al.* (2014). Having calculated each land use footprint through related data, yield factor (YF), intertemporal yield factor (IYF) and equivalence factor (EQF), the total footprint for a country or region is obtained by summing them as given in Eq. (1).

$$EF = \sum_k Footprint_k \quad (1)$$

Following Eq. (1), EF is firstly produced based on production, export and import activities and sum of them yields EF for consumption as shown in Eq. (2).

$$EF_{consumption} = EF_{production} + (EF_{import} - EF_{export}) \quad (2)$$

EF_c represents biologically productive areas consumed by people in a country and it depends on people's consumption behaviors while EF_p indicates some part of it stemming from production activities that can be used as a reflection of gross domestic product (GDP). The sum given in parenthesis is net EF of trade. If export based EF is higher (lower) than import based EF in a country, that country is an exporter (importer) of its own biologically productive areas. The basic procedures to calculate total ecological footprint and biocapacity are depicted in Lin *et al.*, (2016).

YF and EQF become important in relevant calculations to capture differences in land types of countries. More precisely, they are balancing factors that standardize land use types. YF, implying relative productivity, is a ratio of national productivity to World average for a given land type and country while EQF is measured by using GAEZ suitability indexes of the World in terms of land types as average hectares. Thus, EQF allows any area used in EF calculation to be converted into common unit of biologically productive area called a global hectare (gha). On the other hand, IYF is considered to reflect changes in the World average yield over time. In this direction, EF related with a product(EF_p) and BC can be calculated by following Eqs. (3) and (4).

$$EF_p = \frac{P_i}{Y_N} * YF * EQF * IYF \quad (3)$$

$$BC = A * YF * IYF * EQF \quad (4)$$

P_i , Y_N and A notations given in Eqs. (3) and (4) indicate amount of product, national average productivity and area of a given land use type within a country, respectively. EF and BC can be measured as per capita dividing it by total population for a given country as well. Positive or negative difference between BC and EF refers ecological reserve or deficit. According to NFA calculations, more than 80% of world's population experiences ecological deficits. Ecological deficit threatens sustainability and it is considered an unsustainable situation for countries (Pearce and Barbier, 2000).

According to NFA calculations, most recent data shows that demand for nature is 70% more than what the biosphere can regenerate. There is no doubt that this situation mostly arises from non-renewable energy resources since carbon footprint, calculated by CO₂ emissions which are caused by their combustions, forms approximately 60% of humanity's ecological footprint. In this regard, it can be asserted that the best choice to decrease ecological footprint and to contribute sustainability is to meet energy needs through renewable sources. Moreover, considering economic pillar of sustainability and investments costs for renewable energy, biomass may be an efficient tool for sustainable development since it is technically and economically feasible (Bhattacharya *et al.*, 2003; Whalley *et al.*, 2017; Hendricks *et al.*, 2016) as well as an alternative policy that may contribute to increase income and to reduce poverty in developing countries (Demirbas *et al.*, 2009; Bildirici, 2014; Bildirici and Ozaksoy, 2017) and that might help to lessen energy dependence and trade deficits by reducing energy imports (Chalvatzis and Ioannidis, 2017; Ozturk *et al.*, 2017). More importantly, biomass usage, as an alternative to fossil fuels, helps in preventing the environmental threats (such as global warming and climate change) stemming from CO₂ emissions (Dogan and Inglesi-Lotz, 2017). So, it is one of the most prominent renewable energy sources and it is proved that biomass is an effective tool to be able to meet clean energy demand for sustainable development (Sansaniwal *et al.*, 2017).

Literature Review

Especially, in terms of economic and ecological considerations, the substantiality of biomass energy has been an important research topic in the literature (Paine *et al.*, 1996; Caputo *et al.*, 2005; Whalley *et al.*, 2017; Liu *et al.*, 2017). Therefore, based on a great variety of methodologies and observed experiences of countries, biomass energy can be examined from several respects within the frame of sustainable development in the available literature. Some of the relevant literature analyzes efficiency or

potential cost of biomass while some others investigate the role of biomass on CO₂ emissions. On the other hand, some studies focus on growth effect of biomass usage as an alternative energy input and they statistically confirm that biomass usage lead to increase in economic growth (Bildirici, 2013, 2014; Bildirici and Ersin, 2015; Adewuyi and Awodumi, 2017; Bildirici and Ozaksoy, 2017; Aslan, 2016; Shahbaz *et al.*, 2016; Bilgili and Ozturk, 2015; Ozturk and Bilgili, 2015). Eventually, these works highlight that renewable materials, such as biomass, might be imperative to reach sustainable growth. However, the relationship between biomass and emission mitigation is more prior subject in terms of environmental sustainability.

Although some studies notice that bioenergy policies may lead to increase in CO₂ emissions by focusing land use change, carbon leakage, green paradox and some minor adverse effect of biomass on the environment (Piroli *et al.*, 2015; van der Ploeg, 2016; Quentin Grafton *et al.*, 2012; Searchinger *et al.*, 2008; Grafton *et al.*, 2014; Schulze *et al.*, 2012; Repo *et al.*, 2015) the biomass energy is one of the best alternative tools to economically mitigate carbon emissions (Fontaras *et al.*, 2012; Demirbas, 2009; Pradhan and Mbohwa, 2014; McCarl *et al.*, 2010; Liu *et al.*, 2017; Whalley *et al.*, 2017). In this direction, Reinhardt and von Falkenstein (2011) underlined that biofuels are favorable in comparison with fossil alternatives although biofuels might have some negative effect on the environment. However, efficiencies of biofuels and their potential costs for energy conversion may vary from region to region (Fischer *et al.*, 2010; Rogers and Brammer, 2012; Khanna *et al.*, 2011; Furubayashi and Nakata, 2018).

Some econometrical models, as well, have been estimated by several studies to measure the statistical significances of biomass energy on CO₂ emissions in the literature. Based on their sample selections and methodologies, they found negative or positive impact on CO₂ emissions. Ma and Stern (2008) reached important increases in CO₂ emissions in case a shift from biomass to commercial energy by using decomposition analysis for China during 1971–2013. Joelsson and Gustavsson (2010) showed that biomass usage considerably reduces the CO₂ emissions. Bilgili (2012) investigated whether or not biomass consumption can mitigate CO₂ emissions in U.S. for the period 1990:1 and 2011:11 by employing cointegration analyses with unknown regime shifts and confirmed the negative impact of biomass on CO₂ emissions. Taking attention on green paradox, Grafton *et al.* (2014) obtained positive impact on CO₂ emissions for biomass subsidies and biomass production by applying ordinary least squares on the United States' data ranging from 1981 to 2011. Piroli *et al.* (2015) employed a structural VAR approach to analyze the impact of biomass on CO₂ emissions at global level for the period 1961–2009 and they yielded that biofuels significantly reduce global CO₂ emissions. Katircioglu (2015) analyzed Turkey's data from 1980 to 2010 to determine the impact of biomass consumption on CO₂ emissions by conducting bounds test and conditional error correction model and found negative impact. Following the wavelet coherence approach to examine the impact of biomass consumption on CO₂ emissions, Bilgili *et al.* (2016) revealed that biomass consumption improves the quality of environment by reducing CO₂ emissions. For selected European countries, Ahmed *et al.* (2016) obtained positive but insignificant relationship between biomass energy usage and CO₂ emissions by conducting PMG, MG and DFE estimators. Adewuyi and Awodumi (2017) established a simultaneous equation model estimated by three stage least squares for 11 West African countries' data spanning from 1980 to 2010 to investigate the effect of biomass consumption on carbon emissions and their estimations exhibited positive coefficients for 7 out of 11 countries, while negative relationship was obtained just for 4 countries. Dogan and Inglesi-Lotz (2017) employed biomass energy consumption to observe its effect on CO₂ in the panel of biomass-consuming countries by applying panel cointegration and FMOLS estimation techniques for the period 1985–2012 and they concluded that biomass energy consumption mitigates CO₂ emissions. Shahbaz *et al.* (2017) reached the evidence that biomass consumption lowers CO₂ emissions in United States over the period 1960–2016 through ARDL cointegration and VECM Granger causality approaches.

Data, Model and Methodologies

In order to investigate the effect of biomass on proxy indicators of environmental sustainability, this paper mainly follows the models given in Eqs. (5–7) with or without deterministic (or fixed) variables employing annual data spanning from 1990 to 2015 for the UK, Turkey and EU 16 countries:

$$LGHG_{it} = \beta_0 + \beta_1 LEF_{it} + \beta_2 LBiomass_{it} + \beta_3 LFUEL_{it} + \beta_4 LGAS_{it} + u_{it} \quad (5)$$

$$LGHG_{it} = \beta_0 + \beta_1 LEF_{it} + \beta_2 LBiomass_{it} + \beta_3 LGDP_{it} + u_{it} \quad (6)$$

$$LEF_{it} = \beta_0 + \beta_1 LGHG_{it} + \beta_2 LBiomass_{it} + \beta_3 LGDP_{it} + u_{it} \quad (7)$$

The variables LGHG, LEF, LBiomass, LFUEL, LGAS, and LGDP represent the logarithms of Greenhouse Gas Emissions (LGHG), Ecological Footprint (LEF), Biomass energy consumption (LBiomass), fuel consumption (LFUEL), natural gas consumption (LGAS), and GDP (LGDP), respectively.

EF data (1990–2013) is obtained from The Global Footprint Network GFN (2017) as other variable's data are extracted from Eurostat (2018). Additionally, the trend simulations of EF for 2014 and 2015 are also conducted in order for this research to be able to analyze a larger time period.

Since the aim of this study is to examine mainly the interaction between LEF, LBiomass, and LGHG, one might prefer to have a visual inspection of variables that are of primary interest before proceeding to relevant model analyzes.

The Fig. 1 represents the panel data line graph for ecological footprint (EF), which is presented in natural logarithms (LEF). The country level of EF indicates the demand for nature (i.e., demand for land, forest, water sources) within the borders of the country. In other words, the EF of a country, as we underlined before in the text, is an indicator of amount of surface needed by people of

Fig. 1 The movements of LEF panel data: 1990_2015.

Fig. 2 The movements of LGHG panel data: 1990_2015.

relevant country to survive by employing her current technology. Considering 18 countries' panel data for EF, Denmark in 1990, Luxembourg in 2003, Sweden in 2005, and UK during 2001 have relatively greater EF values as Hungary (1992), Italy (2015), Portugal (2013), Spain (2012) and Turkey (2001) have relatively less EF measurements. The panel data reaches the highest peak in 2003-EF value of Luxembourg while the data reaches its lowest value at 2001-EF observation of Turkey.

Fig. 2 plots the line graph for greenhouse gas emissions in logarithmic values (LGHG) within panel data. As is seen from the graph, one might assert that the LGHG spikes up relatively more sharply in observations of Denmark:96; Greece:05; Ireland:01; Portugal:05; Spain:05; and Turkey:15, and that LGHG scales down prominently during 1998 (Luxembourg), 2004 (Belgium), 2013 (Hungary), and, 2015 (Denmark, Germany, Sweden, and, UK).

Fig. 3 depicts the natural logarithms of biomass consumption in panel countries. It appears that the biomass consumption reaches its relatively higher values in 2011 (Netherlands), 2012 (Belgium, Poland and Spain), 2013 (Austria and France) and in 2015 (Germany, Hungary, Italy, Sweden and UK). The biomass consumption, on the other hand, seems to be relatively lower in 1990 (UK), 1991 (Poland and Luxembourg), 1993 (Ireland), and, in 1994 (Belgium).

Fig. 3 The movements of LBiomass panel data: 1990_2015.

After some preliminary graphical observations, several panel data estimation techniques are followed to consider cross-section (i) and time dimensions (t) of the variables. Panel data analyses enable us to control for individual heterogeneity, to give more informative data, more variability, less collinearity, more degrees of freedom and more efficiency (Hsiao, 2003).

Considering panel regression equation, $y_{it} = X'_{it}\beta + u_{it}$, most of the panel data applications utilize one-way error component model for residuals as $u_{it} = \mu + v_{it}$. The first term in this residual component represents unobservable individual specific effects while the second one denotes the remainders that are independent and identically distributed IID $(0, \sigma_v^2)$. Fixed effect and random effect estimators might be launched to estimate panel regression equations. In fixed effect estimations, the μ_i are assumed to be fixed parameters while they are assumed random variables in random effect estimations. However, the variables with large time dimensions included into panel models should be stationary and cross-sectionally independent to be able to reach unbiased and efficient outcome (Baltagi, 2015). Hence, the first step is to check the possibility of cross-correlation of variables. Pesaran *et al.* (2008) proposed a bias adjusted LM test given below for cross-correlation by following Breusch and Pagan (1980).

$$LM_{adj} = \sqrt{\frac{2}{N(N-1)}} \sum_{i=1}^{N-1} \sum_{j=i+1}^N \frac{(T-k)\hat{\rho}_{ij}^2 - \mu_{Tij}}{v_{Tij}} \quad (8)$$

Where $\hat{\rho}_{ij}$ denotes sample estimate pair-wise correlation of the residuals, μ and v are the exact mean and variance of $(T-k)\hat{\rho}_{ij}^2$ respectively. The null hypothesis of the test states “no cross-sectional dependence”. Having applied bias adjusted LM test on the variables, the null hypothesis was strongly rejected for each variable. Results are not presented here to save space, they are, however, available upon request from the authors. The second step is to run the stationarity tests. Under the null hypothesis of non-stationary, Pesaran (2007) proposed cross sectionally augmented Dickey-Fuller test (CADF) in order to take into account the cross-sectional dependence. CADF statistics are obtained by following pth order cross-section/time-series augmented regression.

$$\Delta x_{it} = \psi_i + \zeta_i x_{it-1} + (\phi)_i \bar{x}_{t-1} + \sum_{j=0}^p \phi_{ij} \Delta \bar{x}_{it-1} + \sum_{j=1}^p \beta_{ij} x_{it-1} + \varepsilon_{it} \quad (9)$$

Pesaran (2007) also used IPS test procedure proposed by Im *et al.* (2003) to obtain cross-sectionally augmented IPS test statistics (CIPS) based on the average of CADF statistic for each i . The critical values of CIPS are given by Pesaran (2007). CADF and CIPS statistics of the variables used in this study show that the null of non-stationary cannot be rejected. In the case of non-stationarity, one would get spurious results from the regression equations. Results are not presented here to save space; they are, however, available upon request from the authors. Although the variables of interest might be individually nonstationary, one or more linear combinations of those variables might be stationary (Bai *et al.*, 2009). The next step is, then, to observe if one or more linear combinations of the variables are stationary. To this end, Westerlund (2008) considered two statistics based on the Durbin-Hausman (DH) principle, which takes dependence into account by using common factors. These statistics are calculated through following formulas.

$$DH_g = \sum_{i=1}^n \hat{S}_i \left((\tilde{\varphi})_i - (\hat{\varphi})_i \right)^2 \sum_{t=2}^T \hat{\varepsilon}_{it-1}^2 \quad DH_p = \hat{S}_n \left((\tilde{\varphi}) - (\hat{\varphi}) \right)^2 \sum_{i=1}^n \sum_{t=2}^T \hat{\varepsilon}_{it-1}^2 \quad (10)$$

DH_g and DH_p denote the group mean statistic and panel statistic respectively. $(\tilde{\varphi})_i$ and $(\hat{\varphi})_i$ represent coefficient for one lagged series of error term obtained from the lagged regression of error term (ε_{it}) through OLS and instrumental variables estimators

respectively. $\hat{S}$ depicts variance ratios calculated by Kernel estimator based on OLS residual to variance of OLS estimation. The null hypothesis of DH_g and DH_p tests states "no cointegration". In estimating panel cointegrated regressions Pedroni (2001a,b) and Kao and Chiang (2001) suggested FMOLS and DOLS estimators as given in Eqs. (11) and (12).

$$\hat{\beta}_{FMOLS} = \left[\frac{1}{N} \sum_{i=1}^N \left(\sum_{t=1}^T (x_{it} - \bar{x}_i)^2 \right) \right]^{-1} \times \left[\left(\sum_{t=1}^T (x_{it} - \bar{x}_i) \dot{y}_{it} - T \hat{\Delta}_{eu} \right) \right] \quad (11)$$

Δ_{eu} is a member of covariance matrix to consider serial correlation in interpretation of the asymptotic covariance matrix and $\hat{\Delta}_{eu}$ is kernel estimate of Δ_{eu} . $\bar{x}_i$ refers to the individual specific means. On the other hand, DOLS parameters can be estimated through the regression equation below.

$$\hat{\beta}_{DOLS} = \left[\frac{1}{N} \sum_{i=1}^N \left(\sum_{t=1}^T A_{it} A'_{it} \right) \right]^{-1} \left(\sum_{t=1}^T A_{it} \dot{y}_{it} \right) \quad (12)$$

A_{it} is the $2(K+1) \times 1$ vector of regressors $A_{it} = (x_{it} - \bar{x}_i, \Delta x_{it-K}, \dots, \Delta x_{it+K})$. FMOLS and DOLS estimators are also modified by Kao and Chiang (2001) for heterogeneous panels and they can be used in case there are substantial heterogeneities in cross sections. As a cointegration estimator, Autoregressive Distributed Lag (ARDL) procedure can be used as well. In general framework proposed by Pesaran *et al.* (1999), it is formulated as follows.

$$\Delta y_{it} = b_1 y_{i,t-1} + \tau_i x_{i,t} + \sum_{j=1}^{p-1} \theta_{ij} \Delta y_{i,t-j} + \sum_{j=0}^{q-1} \xi_{ij} x_{i,t-j} + \mu_i + \varepsilon_{it} \quad (13)$$

Besides, the causal interactions among the variables can be estimated by establishing vector error correction model (VECM) based on two-step procedure, that firstly obtains residuals from long run estimation and then includes these residuals as error correction term (ECT) into the VECM, suggested by Engle and Granger (1987). The VECM specification in a bivariate framework can be constructed for panel data as follows.

$$\begin{aligned} \Delta y_{it} &= \theta_{1i} + \gamma_1 ECT_{it-1} + \sum_{p=1}^k \theta_{11p} \Delta y_{it-p} + \sum_{p=1}^k \theta_{12} \Delta x_{it-p} + \varepsilon_{1it} \\ \Delta x_{it} &= \theta_{2i} + \gamma_2 ECT_{it-1} + \sum_{p=1}^k \theta_{21p} \Delta x_{it-p} + \sum_{p=1}^k \theta_{22} \Delta y_{it-p} + \varepsilon_{2it} \end{aligned} \quad (14)$$

where Δ is the first difference operator, k is the optimal lag length(s) proposed by information criteria, p is the lag number. ECT represents error correction term and it is the residuals of long run estimation. The coefficient of ECT (γ_1) is considered as speed of adjustment in correcting disequilibrium for reaching long run equilibrium as well as long run causality.

However, under the heterogeneities and dependencies among cross-sections, bivariate Granger causality analysis proposed by Dumitrescu and Hurlin (2012) may yield more reliable results. Having applied the following equation, Dumitrescu and Hurlin (2012) observed Wald statistics with bootstrap critical values in order to consider dependence.

$$y_{it} = a_i + \sum_{k=1}^K \tau_i^{(k)} y_{i,t-k} + \sum_{k=1}^K \delta_i^{(k)} x_{i,t-k} + e_{i,t} \quad (15)$$

where K is lag order, $K \in N$ and $\delta_i = \delta_i^1, \dots, \delta_i^{(K)}$. It is assumed that lag orders are identical for all cross-sections while $\tau_i^{(k)}$ and $\delta_i^{(k)}$ are allowed to differ across units. The null and alternative hypotheses are defined as:

$$H_0 : \delta_i = 0, \forall i = 1, \dots, N \quad H_1 : \begin{cases} \delta_i = 0 \forall i = 1, \dots, N \\ \delta_i \neq 0 \forall i = N_1 + 1, N_1 + 2, \dots, N \end{cases} \quad (16)$$

The null hypothesis states that the variable x does not granger cause the variable y for all individuals of the panel and rejection of the null ($N_1=0$) implies that x Granger causes y for all units of the panel. Employing the average of Wald statistics for all units $i=1, \dots, N$, the existence of no Granger causality for all sections is tested under the null hypothesis against the alternative meaning that at least one causal relationship exists ($N_1 > 0$) in the panel data. If $N_1 > 0$, the causality relationship between x and y differs from one cross-section to another and the alternative hypothesis yields heterogeneous results.

Estimation Output

This research paper mainly considers analyzing the data for 18 European Countries to observe (i) the impact of biomass energy source on Greenhouse Gas emissions, (ii) the influence of biomass energy consumption on ecological footprint, (iii) the effect of ecological footprint on Greenhouse gas emissions, and, (iv) the impulse of Greenhouse gas emissions on ecological footprint. The regarding results are obtained through MATLAB and RATS program's lines.

**H₀: The null is the Homogenous non Causality (HNC) hypothesis from X to Y.

In this paper, all estimations are conducted by launching logarithmic forms of the relevant variables. The paper first analyzes the Dumitrescu-Hurlin panel causalities (a) from LEF to LGHG, (b) from LGHG to LEF, (c) from LBiomass to LEF, (d) from LEF to LBiomass, (e) from LBiomass to LGHG, and, (g) from LGHG to LBiomass.

$\bar{W}$ depicts the mean value of the N individual Wald statistics. Wald statistic follows asymptotically χ^2 (chi-squared) distribution. Under some circumstances, individual Wald statistics may not follow standard χ^2 distribution. However, Dumitrescu and Hurlin (2012) showed in general that individual Wald statistics are independently distributed with finite second order moments. The $\bar{Z}$ and $\tilde{Z}$ statistics denote standardized statistic and approximated standardized statistic, respectively, for the mean value of the N individual Wald statistics.

Table 1a reveals the output of Dumitrescu-Hurlin panel causality tests from Ecological Footprint (LEF) to Greenhouse Gas Emissions (LGHG). The null hypothesis (H₀) is the Homogenous non Causality (HNC) hypothesis from LEF to LGHG. According to $\bar{W}$, $\bar{Z}$ and $\tilde{Z}$ statistics, there exists significant causality from LEF to LGHG. The statistics of $\bar{W}$, $\bar{Z}$ and $\tilde{Z}$ are significant at 1% level. Hence, one can claim that LEF causes LGHG significantly. The LEF is found significant in determining the LGHG values. Then, one can argue that LEF should precede the future values (leads) of LGHG. **Table 1a** also depicts that there exists also significant causality from LGHG to LEF. The statistics of $\bar{W}$, $\bar{Z}$ and $\tilde{Z}$ explored that LGHG causes LEF. **Table 1a** eventually indicates that there exists bilateral causality from LEF (LGHG) to LGHG (LEF). This result confirms the expectation that carbon emission (LGHG) and environmental degradation (LEF) are closely associated.

**H₀: The null is the Homogenous non Causality (HNC) hypothesis from X to Y.

Table 1b yields significant the individual effects of LEF on LGHG in Austria, Belgium, Denmark, Greece, Hungary, Italy and Spain. **Table 1b**, then, exhibits the outcome that the variable LEF can predict significantly the future values of LGHG in these countries. The **Table 1b** also depicts the individual results that the past values of LGHG can forecast significantly the future values of LEF in Denmark, Finland, France, Germany, Luxembourg and Turkey.

Table 2a shows the outcome of Dumitrescu-Hurlin panel causality tests among the pairs of variables LBiomass and LEF. The **Table 2a** indicates that LBiomass (LEF) causes LEF (LBiomass). The $\bar{W}$, $\bar{Z}$ and $\tilde{Z}$ statistics have the p values of 0.000 verifying the bivariate significant causalities between LBiomass and LEF.

The **Table 2b** presents the significant individual country impact of LBiomass on LEF in Denmark, France, Germany, Italy, Netherlands, Portugal, Spain, Sweden and Turkey. In other word, the effect of renewable energy of biomass consumption on ecological footprint is found considerable in 10 out of 18 countries in European continent. **Table 2b** shows, on the other hand, the significant cross section impact of LEF on LBiomass in the countries of Belgium, Germany, Hungary, Netherlands and Spain. **Table 2b**, then, confirms relatively more the influence of biomass energy usage on ecological degradation than the impulse of ecological degradation on biomass consumption in Europe.

Table 3a reveals the significant causalities between LBiomass and LGHG. The relevant $\bar{W}$, $\bar{Z}$ and $\tilde{Z}$ statistics are found significant at 1% level. **Table 3b** gives the conclusion of Dumitrescu-Hurlin cross unit individual causality tests from LBiomass to LGHG and the individual causality tests from LGHG and LBiomass. The table exhibits that the 13 countries out of 18 countries in Europe experience statistically significant causality from biomass consumption to carbon emission. These countries in which LBiomass consumption causes LGHG emissions are Belgium, Denmark, France, Germany, Greece, Hungary, Ireland, Italy, Netherlands, Portugal, Spain, Sweden, and UK, respectively.

The following **Tables 4, 5, 6** and **7** yield the sign of the causalities between the pair of variables. **Table 4a** and **Table 4b** give the output from panel regression estimation by fixed effects and panel regression estimation by random effects. According to **Table 4a**, LBiomass has negative impact on LGHG as LEF, LFUEL and LGAS have positive influences on LGHG. Considering long run fixed effect output, one may state that as LBiomass increases 1 percent, the LGHG will decrease by 0.0382 percent.

The long run biomass elasticity of Greenhouse gas emissions is statistically significant, has expected negative sign and is less than unity. The long run LEF, LFUEL and LGAS elasticities of LGHG are 0.5304, 0.1384 and 0.0671, respectively. In the long run, 1% increase in LEF variable causes LGHG to increase by 53.04%. Fuel energy consumption has also considerable positive impact on carbon emissions (0.1384). In the short run, the error correction term (EC) is found significant and negative. The EC term denotes one period lagged residuals (u,t-1) from the relevant long run equilibrium. The coefficient of EC is expected to be

significant and negative in order for LGHG to be able to restore its equilibrium. For instance, the residual in 2014 of cross section UK is -0.061887 . It means that LGHG is below its long run equilibrium value. Then LGHG will increase by 0.008992181 [$= (-0.1453) \times (-0.061887)$] in UK to restore its long run equilibrium. In the short run, all variables, except Δ LBiomass, are significant and affect Δ LGHG positively.

*depicts 1% statistical significance. (Standard errors are given in parentheses).

Table 4b indicates that the output of panel regression estimation by random effect methodology is similar to that of panel regression estimation by fixed effect methodology. The random effect results, hence, yield that biomass consumption has negative influence on emissions whereas EF, fuel and gas have positive impact on emissions in the long run. In the short run, the error correction term is significant and has negative sign. This output underlines the statistical evidence that the deviation from long run equilibrium will be restored by the amount of $[(- 0.1466) \times (u, t-1)]$. In the short run, Δ LEF, Δ LFUEL, and Δ LGAS have positive impulses on Δ LGHG. The Δ LBiomass' standard error value of 0.0115, hence, t value of 0.53 reveal that Δ LBiomass appears to be insignificant in the short run.

Tables 5a and **5b** follow fixed effect and random effect estimations, respectively, to observe the effects of log of biomass and log of ecological footprint as log of GDP is added into model. **Table 5a** explores that (i) as LEF goes up by 1%, the LGHG goes up by 0.4474%, (ii) when LBiomass increases 1%, the LGHG diminishes by 0.1102%. The results of **Table 5a** and **Table 5b** are very close to each other. **Table 5b** yields the LEF (0.4407) and LBiomass (– 0.1048) elasticities of LGHG.

The EC term is significant with the values of – 0.1586 (**Tables 5a**) and – 0.1569 (**Table 5b**). As Δ LBiomass happens to be insignificant in the short run as given in **Tables 5a** and **5b**, (i) the LEF and LGDP have positive significant impacts on LGHG in both **Table 5a** and **Table 5b**, (ii) the short run slope coefficient estimates of LEF and LGD are 0.1547 and 0.3249, respectively (**Table 5a**), (iii) the short run slope coefficient estimates of LEF and LGDP are 0.1539 and 0.32610, respectively (**Table 5b**).

Table 6 shows the panel cointegration regression estimations through FMOLS and DOLS models. The upper part of the table yield the estimation with deterministic variables of constant, LFUEL and LGAS, while lower part of the table gives the estimated coefficients through deterministic variables of constant, LFUEL, LGAS, and, LGDP.

In upper part, the regression output from FMOLS models indicate that a unit % expansion in LEF advances LGHG by 0.2857% and a unit % increment in LBiomass lowers the LGHG by 0.0515%. The relevant DOLS estimations for LEF and LBiomass are 0.2843 and – 0.0712, respectively. The below part of the table exhibits the outputs of FMOLS and DOLS that are similar to those of upper part of the table in terms of signs. The magnitudes of estimations are close to each other.

Table 7a and **Table 7b** depict the significant impulses of LEF and LBiomass on LGHG through ARDL estimations. As in previous tables, **Tables 7a** and **7b** confirm as well, that biomass usage decreases carbon emissions whereas ecological footprint boosts the emissions. The long run equilibrium estimated coefficients of LEF and LBiomass are 0.23401 and – 0.0730, respectively (**Table 7a**). The short run estimations reveal that EC term is found significant and that, among other short term changes, only the

short term change in biomass (Δ LBiomass) variable is significant at 1% level. In the short run, biomass usage appears to affect the greenhouse gas emissions positively (Table 7a). Employing the fixed variables of constant, LFUEL, LGAS, and LGDP, Table 7b explores the positive consequences of LEF and LBiomass on LGHG in the long run at 1% level, and positive consequence of Δ LBiomass and negative power of Δ LGHG(– 1) on Δ LGHG in the short run at 10% significance levels.

From the output of Table 4a to the output of Table 7b, this paper concludes that LEF deepens LGHG whereas LBiomass declines LGHG. Since this paper also considers the causalities from GHG and Biomass to EF, the following Tables 8a, 8b, 9, 10a and 10b give the sequences of greenhouse gas emissions and biomass consumption on ecological footprint.

In Table 8a, the panel regression estimations by fixed effects reveal that there exist significant positive effects of logs of greenhouse gas emissions and GDP on log of ecological footprint both in the long run and short run. The log of biomass consumption is found insignificant in determining the long run and short run values of log of ecological footprint.

In **Table 8b**, the panel regression estimations through random effects yield positive influences of LGHG and LGDP on LEF at 1% levels, and, negative impulse of LBiomass on LEF at 10% level. **Table 8b** verifies **Table 8a** in terms of statistical significances and signs of LGHG, LGDP and EC term in the short run.

Table 9 shows the panel cointegration regression estimation by FMOLS and DOLS models. The outcome indicates that LGHG affects significantly and prominently the LEF when constant, LFUEL and LGAS are employed as deterministic variables. On the other hand, LGHG intensifies LEF and LBiomass lessens LEF in the long run, when the constant term, and LFUEL, LGAS and LGDP variables are considered deterministic variables within the models of FMOLS and DOLS. The estimated significant parameters of LGHG and LBiomass from FMOLS are 0.5265 and – 0.0797, respectively. The estimated significant

coefficients of LGHG and LBiomass from DOLS are 0.5285 and – 0.1135, respectively. Regarding DOLS results, one can indicate that the LEF increases by 0.5285% in response to one percent increase in LGHG, and, reduces by 0.1135% in response to one percent increase in LBiomass.

Table 10a exhibits the output from panel ARDL regression estimations and states that LGHG affects positively the LEF with the estimated coefficient of 0.9449 and LBiomass affects negatively LEF variable with the estimated parameter of – 0.0126. In the short run equilibrium, only EC and constant terms appear to be significant.

Table 10b demonstrates the positive impact of LGHG on LEF and negative effect of LBiomass on LEF in the long run. The estimated cointegration equilibrium coefficients of LGHG and LBiomass are 0.8578 and – 0.0226, respectively.

If EC term is not significant and not negative, there exists no long run relationship between LEF, LGHG and LBiomass. In the short run, Δ LEF responses significantly to lagged variables of Δ LEF, Δ LGHG [Δ LEF(– 3), Δ LGHG(– 2)], and EC and constant terms.

The EC term is significant at 1% level and has the value of – 0.8610. One may observe, for instance, the residual from Swedish data estimation in 1994 (= – 0.028751), among 18 European countries' panel data, and indicate that the LEF long run equilibrium will increase in 1995 by 0.02475 percentage [– 0.028751 $\times$ – 0.8610] to restore its cointegrating relationships with LGHG and LBiomass. Or, again, let one observe, by coincidence, the residual from Turkish data estimations in 2014 (= – 0.003132). It would mean that the LEF was below its cointegrating equilibrium level in 2014 by 0.003132 units and that, hence, LEF would increase in 2015 by 0.002696 units to keep its long run equilibrium.

Conclusion

This paper mainly aims at estimating the determinants of environmental degradation by analyzing the panel data for 18 European Countries. The paper, then, observes (i) the impact of biomass energy source on Greenhouse Gas emissions, (ii) the influence of biomass energy consumption on ecological footprint, (iii) the effect of ecological footprint on Greenhouse gas emissions, and, (iv) the impulse of Greenhouse gas emissions on ecological footprint.

To this end, the paper follows panel data methodologies. The paper first analyzes the Dumitrescu-Hurlin panel causalities (a) from LEF to LGHG, (b) from LGHG to LEF, (c) from LBiomass to LEF, (d) from LEF to LBiomass, (e) from LBiomass to LGHG, and, (g) from LGHG to LBiomass.

The output, for instance, exhibits that the 13 countries out of 18 countries in Europe experience statistically significant causality from biomass consumption to carbon emission. These countries in which LBiomass consumption causes LGHG emissions are Belgium, Denmark, France, Germany, Greece, Hungary, Ireland, Italy, Netherlands, Portugal, Spain, Sweden, and UK, respectively.

Fixed and random effect models indicate that log of biomass consumption has negative influence on log of emissions whereas logs of EF, fuel and gas have positive impact on log of emissions in the long run.

FMOLS models indicate that 1% expansion in LEF advances LGHG by 0.2857% and 1% increment in LBiomass diminishes the LGHG by 0.0515%. The relevant DOLS estimations for LEF and LBiomass are 0.2843 and -0.0712 , respectively.

ARDL estimations confirm the previous estimation and yield that biomass consumption lowers GHG emissions whereas ecological footprint boosts the emissions. The long run equilibrium estimated coefficients of LEF and LBiomass are 0.23401 and -0.0730 , respectively.

The panel regression estimations through random effects reveal positive impacts of LGHG and LGDP on LEF at 1% levels, and, negative impulse of LBiomass on LEF at 10% level.

FMOLS and DOLS estimations exhibit the output that LGHG increases LEF and LBiomass diminishes LEF in the long run. The DOLS results, for instance, indicate that the LEF increases by 0.5285% in response to 1% increase in LGHG and decreases by 0.1135% in response to 1% increase in LBiomass.

ARDL output verifies FMOLS and DOLS results by stating that long run impacts of LGHG and LBiomass on LEF are 0.8578 and -0.0226 , respectively.

Throughout the panel estimations, this paper suggests that policy makers support more biomass energy production and consumption in EU-18 countries to mitigate greenhouse gas emissions and hence environmental degradation. This possible action that might be taken by EU administrators might enable EU societies to reach sustainable growth.

Introduction

Energy is an essential requirement for human in the current scenario to sustain the living standards and to enhance the economics of the nation. So far, the energy need was fulfilled by the fossil based fuels like petroleum products, natural gas and coal etc. Due to rapid industrialization and population growth the demand for the energy is increased more whereas energy supply from fossil fuels is decreased since it is non-renewable resource. The alternate renewable sources have been gaining interest to overcome the energy crisis due to the exhaustion of fossil fuels. Biodiesel is mainly focused as an alternative fuel source since it possesses serial advantages like less carbon dioxide emission, non-toxic and better efficiency. Mono-alkyl esters of fatty acid obtained from the transesterification reaction of oil and alcohol in the presence of catalyst is known as biodiesel. It shows similar properties of the conventional petroleum fuel and it is produced mainly from the edible oils. Use of edible oils for large scale biodiesel production is limited since it imbalances the global food demand. Non-edible oils were employed as an alternate source to edible oils because they are economic, easily available and do not affect the food industrial demand. Various non-edible oils such as jatropha, karanja, palm, mahua, moringa and rubber seed etc were used for production of clean, eco-friendly biodiesel nowadays.

Optimization is one of the key steps in any process since it directly influences the product yield and economics. The variables or conditions involved in the process should be optimized to get maximum yield with optimal resources. Previously, conventional one-variable at a time (OVAT) method is preferred for optimization studies but it lacks to provide the details of interaction effect of variables, require more time and experiments. Statistical experimental designs are very effective for multivariate optimization which gives better insight about the variables interaction and its optimal levels. Response Surface Methodology (RSM) is a most widely used successful statistical optimization tool to make experimental design, model the process, study the combined effects of variables and identify the optimum levels. In this report, utilization of RSM for optimization of biodiesel production from Jatropha oil was discussed.

The kinetics of the reaction is very important to determine the rate constant and the mechanism which are useful for designing an appropriate reactor for production. For biodiesel production, transesterification is an important reaction for the synthesis of alkyl ester from the reaction of oil and solvent in the presence of catalyst. The reaction rates were highly influenced by the type of catalyst involved in the reaction. For homogeneous catalyzed transesterification, usually the kinetics followed first or second order models. In case of heterogeneous catalyst reaction rate follows different mechanism. The study of different kinetic models for biodiesel production provides the details about the reaction mechanism and rate controlling step in transesterification. In this chapter, different kinetic models used to determine the reaction rate for biodiesel production was also discussed.

Jatropha Oil

Jatropha curcas (Linnaeus) belongs to Euphorbiaceae family and widely planted as an economic crop. Jatropha is easy to grow and it is tolerant to stress and drought. Different parts of the plant such as bark, fruit and seeds were used for several applications in medicine and energy production. *Jatropha curcas* seeds are found to be the richest source of oil provides the highest productivity of biodiesel. Moreover, American and European standards organisation confirmed the quality of jatropha biodiesel and they are very well comparable with the commercially available fossil fuels. The productivity of biodiesel from crude jatropha oil can be improved by optimizing the conditions required for the conversion of seed oil to methyl ester of fatty acids.

Response Surface Optimization of Jatropha Oil Based Biodiesel Production

Yee *et al.* (2011) reported a maximum biodiesel yield of 90.32 wt% produced by optimizing the process variables such as reaction temperature, time, molar ratio of methanol to jatropha oil and concentration of catalyst: alumina loaded with sulphated zirconia. The optimization study was conducted using Design Expert software to analyse the process variables based on Response Surface Methodology. The coefficient of variation decides the quality of the model and it was found to be 98.66% with a confidence level of 95% analysed through ANOVA. The study on influence of interaction effects of process variables on biodiesel yield was conducted with fixed catalyst loading of 6 wt% and methanol to oil ratio at 8. It was observed that on increasing the temperature from 90°C to 150°C there is a gradual increase in the yield of biodiesel from 25.59% to 60.21% and with the same trend the duration time increased to 4 h the biodiesel yield was shoot up to 74.74%. Hence it was concluded that the reaction duration have more impact on the biodiesel yield at higher temperature rather than at lower temperature. Similarly at higher reaction

temperature of 150°C, the raise in methanol to oil ratio from 6 to 10 leads to increase the biodiesel yield from 57.19% to 75.05%. The characterization studies proved that the fuel properties of Jatropha biodiesel met with the standards as per ASTM D 6751.

A two step processes for biodiesel production using crude jatropha oil was experimented by [Gandhi and Kumaran \(2014\)](#). The first step involves the acid treatment to reduce the free fatty acid content from 6.85% to 1.12% and the second step comprised of RSM based optimization to the transesterification process of pretreated jatropha oil. A central composite rotatable second-order design was implemented to analyse the process variables with three factors at 5-levels to derive the ANOVA report and interaction effects via response surface plots. The results of ANOVA suggested that the model is significant as the p-value obtained is below 0.0001 with R^2 value of 0.9722. The 3-D plots depict the effects of interaction of process variables on biodiesel yield. The interaction effects were demonstrated by changing two process variables by keeping one as constant value to predict the biodiesel yield. In this way the experiments were conducted by changing the reaction temperature and methanol to oil ratio with the fixed concentration of catalyst (0.55%). The results suggested that the reaction temperature was found to be reciprocal with the methanol to oil ratio. By increased methanol to oil ratio at lowest temperature the yield of biodiesel was found to be high and vice versa. Similarly the interaction effects were studied for the change in catalyst concentration and reaction temperature with fixed concentration of methanol to oil ratio (1:5.41). These results depicts that the biodiesel yield was increased till 62°C and 0.58% of catalyst concentration and beyond that there was a decline in the biodiesel yield. A highest yield of 92.5% was achieved under the reaction temperature of 61.5°C, catalyst concentration of 0.58% w/w and 1:5.93 molar ratio of oil to methanol.

Jatropha biodiesel production up to 98.3% with reduced free fatty acid from 14.6% to 0.34% was produced by [Goyal et al. \(2012\)](#). To achieve this yield, four process variables such as methanol/oil molar ratio, reaction time, reaction temperature and catalyst concentration at five level was employed using central composite design (CCD) of RSM. The optimization of the experimental conditions using RSM was performed with two-step processes. In the first step, optimization involves the reduction of free fatty acid content to 0.34% achieved at optimum temperature of 50°C for 125 min reaction with 1.5% v/v sulphuric acid as catalyst and methanol/oil in 6.5:1 molar ratio. The ANOVA table was framed for the esterification process and it was showed with the p-value less than 0.0001, which indicated that the model was significant. The model also proved as goodness of fit, as the regression co-efficient value for the experimental model was found to be 0.96 and which was near closer to the model predicted value of 0.92. The impact of the catalyst concentration, temperature, time and methanol/oil ratio on FFA content was demonstrated by calculating the deviation of the coded value from the middle point of the respective process variables. It was observed that increase in concentration of catalyst decreases the FFA content and whereas, the methanol/oil ratio have no effect on the change in FFA content. The FFA was found to be decreased with increase in time and temperature till middle point after that it was increased. These results indicated that longer incubation time and exposure to higher temperature leads to inhibition of FFA reduction. The effect of process variables in esterification process was demonstrated that the second step optimization is yield improving step, includes the optimum range of process variables such as 11.1 methanol/oil molar ratios, 1% w/w of sodium hydroxide reacted for 110 min at reaction temperature of 55°C. This trans-esterification step also showed a p-value lower than 0.0001 with a goodness of fit regression values of 0.945, which was greater than the model predicted value of 0.890 indicated that the model is more significant. To determine the efficiency of trans-esterification process for biodiesel production, a similar kind of deviation with coded value of process variables from the middle point was studied. It was understood that the biodiesel productivity was increased with increase in concentration of methanol and time, indicated that increasing the processing time along with methanol ratio ensures the complete transformation of the fatty acid esters to biodiesel. At initial stage the increase in temperature decreases the biodiesel yield but after the reaction proceeds the production of jatropha biodiesel was improved with increasing temperature. This results suggested that initial period the viscosity of the oil decreases the biodiesel productivity and later on the viscosity decreases with time and hence the productivity of the biodiesel improved with higher temperature. A maximum yield of 98.3% of jatropha biodiesel was produced and it was confirmed with ASTM standard requirements.

Microwave assisted biodiesel yield improvement was demonstrated by [Jaliliannosrati et al. \(2013\)](#). The parametric variables include particles seed size, irradiation time, stirrer speed and catalyst loading. Response Surface Methodology (RSM) based Central Composite Design (CCD) was used to design the experimental variables. The reaction was induced by using 5N potassium hydroxide solution as base catalyst. Initially the free fatty acid present in the oil was reduced to 1% from 14% by treating with catalyst, sulphuric acid and the reduced free fatty acid was subjected for optimization to yield 97.29% of fatty acid ethyl esters. The RSM design was generated by incorporating four independent variables such as irradiation time, agitation speed, catalyst loading and size of the particles. The experimental results were analysed by ANOVA report and response surface plots to justify the significance of the model. A smaller p-value of 0.005 indicated that the model is significant but the value of 'lack of fit' was found to be 0.2870 revealed the insignificant of the model. The surface and contour plots were used for determining the interaction effects for irradiation time versus agitation speed and catalyst loading versus agitation speed against the conversion of free fatty acid. To study the interaction effect, irradiation time was fixed at constant up to 20 min; the agitation speed and catalyst loading varied from 150 to 350 rpm and 8–10 mL respectively. It was found that beyond 300 rpm speed and 9 mL of catalyst loading there is no improvement in the FFA conversion. Similarly 9 mL of catalyst loading was fixed with varying the irradiation time and speed of 12–28 min and 150–350 rpm respectively. The results suggested that lesser the irradiation time for 10–12 min and agitation speed about 300 rpm is sufficient for the successful conversion of FFA. The optimum conditions for the process include less than 0.5 mm of seed size, time of irradiation 12.21 min. with 110 W microwave power, potassium hydroxide catalyst loading of 8.15 ml and stirrer speed of 331.52 rpm.

Calcium oxide coupled with magnesium oxide was employed as synergetic catalyst for transesterification of jatropha plant oil in production of biodiesel. The novel catalyst has proved its incredible effect in improved production of biodiesel of 93.55%. A highest order polynomial with greater significant, a quadratic model suggested by CCD based RSM was utilized for the determination of interaction effects by surface and contour plots. A 95% of confidence level with p-value less than 0.0001 depicted that the model suggested was statistically significant. The ANOVA results suggested that time of reaction (A), Methanol to oil ratio (B), Temperature (C) and Catalyst concentration (D) are the variables having significant influence in conversion of fatty acid methyl esters. The interaction terms such as AD, AC and CD have major impact on increasing conversion of fatty acid demonstrated by 3-D surface plots. The p-value obtained for the lack of fit test is greater than 0.05 indicated that the model is not significant but the coefficient of variation and R^2 value is 3.99% and 98.9% respectively, and this suggested that the model possess high degree of precision and reliability. The combined catalysts along with the following optimum conditions generated by CCD, such as methanol to oil molar ratio of 38.67, catalyst loading of 3.7% w/w along with 115.87°C temperature and 3.44 h of reaction time respectively contributed high production of biodiesel. Lee *et al.* (2011), has proved that the high yield of biodiesel is due to the synergetic effect of the coupled active catalysts CaO-MgO.

The CCD based optimum conditions with 0.62% v/v of ethanol to oil molar ratio, 1.7% v/v of acid catalyst using sulphuric acid, 79 min of processing time and operating temperature at 54°C was provided to reduce the FFA from 14% to 1%. A quadratic polynomial model was utilized to relate the reaction variables with the FFA reduction showed better coefficient of determination $R^2=0.893$. Suwito *et al.* (2012) proved that these results were comparable with transesterification process utilizing a base catalyst. According to the ANOVA results it was noted that the ethanol to oil ratio one exhibited the significant effect on reduction of FFA at confidence level of 95%. The interaction effects of process variables on the biodiesel productivity suggested that the catalyst concentration between 1% and 3% with increase in ethanol to oil concentration greatly increases the FFA reduction. Another interactions between time and ethanol to oil ratio indicated that the concentration of ethanol beyond 0.5% and time of 90 min enhances the reduction of FFA.

Kombe and Temu (2017), utilized two process variables to optimize the deacidification efficiency of jatropha oil up to 98.74% using CCD based RSM. The two independent process variables employed in the study were amount of steam and reaction temperature which yielded a 13 runs of CCD based RSM design. The steam distillation efficiency for the conversion of free fatty acid into biodiesel was determined from the results of surface plots and the ANOVA. The p-value less than 0.005 and the coefficient of determination $R^2=0.9563$ highly supports the model is statistically significant. The 3-D surface plots results suggested that the interaction effect of amount of steam and reaction temperature 3.4 wt% and 235°C yielded a maximum transesterification of free fatty acid. The optimized conditions reduce the high FFA of crude jatropha oil to a value near to 0.09% from 4.54%. The deacidified jatropha oil was transesterified by homogenous base catalyst to produce biodiesel of 97.45%. The fuel produced was tested for the viscosity, acid value, total calorific value, FAME, density and iodine value to prove that the biodiesel obtained from jatropha oil through this optimization study was very well comparable with the EN14214 and ASTM D6751.

Kinetic Modeling of Biodiesel Production

Transesterification Reaction

Transesterification is a chemical reaction where alkoxy group of an ester and alkoxy group of an alcohol is exchanged in the presence an acid or a base catalyst. In the case of biodiesel production, three moles of triglycerides (TG) in animal fats or vegetable oil reacts with alcohol (methanol or ethanol) to yield one mole of glycerol and three moles of fatty acid methyl ester (FAME) or fatty acid ethyl ester (FAEE) (Fig. 1). If methanol is used as alcohol in biodiesel production, the product is methyl esters (ME); likewise, if ethanol is used as alcohol, the reaction product will be ethyl esters (EE). But, in both, glycerin is the co-product of transesterification. The reaction are shown below,

Generally, transesterification reaction consists of three successive reversible reactions; in each step one mole of ME is generated along with monoglycerides (M) and diglycerides (D) as intermediates during first and second steps respectively (Fig. 2). Transesterification of TG with methanol is catalyzed by acid or base catalyst, where acid and base catalyst could be either homogenous or heterogeneous catalyst.

Transesterification, catalyzed by heterogeneous catalyst is more complex reaction (reaction proceed on the surface of solid catalyst) since it is three phase liquid-liquid-solid reaction. Therefore, rate of biodiesel depends on seven steps such as,

- (1) External diffusion of reactant,
- (2) Internal diffusion of reactant,
- (3) Adsorption of reactant on the catalyst surface,
- (4) Surface reaction,
- (5) Desorption of product,
- (6) Internal diffusion of product and
- (7) External diffusion of product.

Kinetics for transesterification reactions of TG are examined by numerous researchers. Theses researches mainly focused to generate equation for rate of reaction. These developed rate kinetics are very much useful in the design of reactors in the biodiesel

Fig. 1 Scheme of transesterification reaction.

Fig. 2 Three steps involved in Transesterification of TG and methanol.

production. Different rate equation has been developed by various scientists depends on the types of catalyst used in the transesterification reaction. For Homogenous catalyst, generally, first order and second order kinetics are developed. On the other hand, for heterogeneous catalyst Eley-Rideal kinetics and Langmuir- Hinshelwood-Hougen-Watson (LHHW) are developed. In the case of catalytic reaction, controlling step could be surface chemical reaction or adsorption of reactants or desorption of reactants or internal diffusion or external diffusion.

Kinetic Models for Homogeneous Catalyzed Transesterification

Pseudo-First Order Kinetics Model

This kinetic model rests on the following assumptions

- (1) The transesterification reaction occurs in the oil phase. i.e., oil is the limiting reactant,
- (2) Transesterification reaction is carried out in the presence of large quantity of methanol (excess reactant),
- (3) The slowest step (rate limiting step) is reaction between TAG and one mole of methanol.

Table 1 Summary of pseudo-first order rate constants for transesterification of TG

Oil	Catalyst	Rate constant (min^{-1})	Activation energy (kJ mol^{-1})	References
<i>Bombax ceiba</i> oil	CaO-NPs	0.031	35.99	Hebbbar <i>et al.</i> (2018)
<i>Madhuca indica</i> oil	KOH	0.011	22.31	Muthukumaran <i>et al.</i> (2017)
Sunflower oil	Al-Sr NPs	0.012	72.86	Feyzi and Shahbazi (2017)
Soybean oil	H ₂ SO ₄	0.003	27.53	Parkar <i>et al.</i> (2012)
Waste cooking oil	NaOH	0.078	88.76	Jain <i>et al.</i> (2011)
Rapeseed crude oil	NaOH	0.696	85.4	Wang <i>et al.</i> (2007)

Based on the assumption stated above the following rate equation could be written as:

$$-r_{TG} = -\frac{dC_{TG}}{dt} = kC_{TG}C_{MOH} \quad (1)$$

Since, methanol is added into reaction mixture as excess reactant, the simplification could be made,

$$k' = kC_{MOH} \quad (2)$$

Substituting Eq. (2) into the Eq. (1) result to,

$$-r_{TG} = -\frac{dC_{TG}}{dt} = kC_{TG} \quad (3)$$

Conversion (X_{TG}) with respective TG could be defined as,

$$X_{TG} = \frac{C_{TG0} - C_{TG}}{C_{TG0}} \quad (4)$$

$$\therefore dC_{TG} = -C_{TG0}dX_{TG}$$

Substituting the Eq. (4) into (3) and integrating with the boundary condition as when time=0 $X_{TG}=0$ and when time=t; $X_{TG}=X_{TG}$

$$-1n(1 - X_{TG}) = k't \quad (5)$$

Further, the activation energy necessary to proceed with the transesterification reaction could be calculated using Arrhenius equation as given below (Table 1),

$$k = k_0 e^{-E_a/RT} \quad (6)$$

Second Order Kinetics

Transesterification of TG could be modelled with second order differential equation based on the elementary reaction mentioned in the stoichiometry represented in Eq. 7–12. Table 2 showed second order the rate constants reported in different studies on biodiesel production.

$$-r_{TG} = \frac{dC_{TG}}{dt} = k_1 C_{TG} C_{MOH} - k_2 C_{FAME} C_{DG} \quad (7)$$

$$-r_{DG} = \frac{dC_{DG}}{dt} = k_2 C_{FAME} C_{DG} - k_1 C_{TG} C_{MOH} + k_3 C_{DG} C_{MOH} - k_4 C_{FAME} C_{MG} \quad (8)$$

$$-r_{MG} = \frac{dC_{MG}}{dt} = k_4 C_{FAME} C_{MG} - k_3 C_{DG} C_{MOH} + K_5 C_{MG} C_{MOH} - k_6 C_{FAME} C_G \quad (9)$$

$$r_{MOH} = \frac{dC_{MOH}}{dt} = k_1 C_{TG} C_{MOH} - k_2 C_{FAME} C_{DG} + k_3 C_{DG} C_{MOH} - k_4 C_{FAME} C_{MG} + K_5 C_{MG} C_{MOH} - k_6 C_{FAME} C_G \quad (10)$$

$$r_{FAME} = \frac{dC_{FAME}}{dt} = k_1 C_{TG} C_{MOH} - k_2 C_{FAME} C_{DG} + k_3 C_{DG} C_{MOH} - k_4 C_{FAME} C_{MG} + K_5 C_{MG} C_{MOH} - k_6 C_{FAME} C_G \quad (11)$$

$$r_G = \frac{dC_G}{dt} = K_5 C_{MG} C_{MOH} - k_6 C_{FAME} C_G \quad (12)$$

Table 2 Summary of second order rate constant for transesterification of TG

$S.G \leftrightarrow S + G$	$\frac{k_{-7} \left(\frac{k_6 K_1 C_M C_{MOH}}{C_{FAME}} \right) - k_7 C_G}{1 + K_1 C_{MOH} + K_3 C_D + K_5 C_M + \frac{k_6 K_1 C_M C_{MOH}}{C_{FAME}}}$

Modified from Kapil, A., Wilson, K., Lee, A.F., Sadhukhan, J., 2011. Kinetic modeling studies of heterogeneously catalyzed biodiesel synthesis reactions. *Industrial & Engineering Chemistry Research* 50 (9), 4818–4830.

Kinetic Models for Heterogeneous Catalyzed Transesterification

Eley-Rideal Kinetics

The elementary step involved in the Eley-Rideal model shown in **Table 3**. In this, methanol is adsorbed on (M) on the vacant site of catalyst(S), these adsorbed methanol subsequently interact with T, D, M (which are in the bulk fluid) and results adsorbed diglyceride (S.D), monoglyceride (S.M), and glycerol (S.G) respectively, along with FAME in each step. Each of the above step can be considered as rate controlling step. The kinetic expressions given in **Table 3** was developed by making the following assumptions.(i) Surface of catalyst is homogenous without the inert species on the surface and (ii) Slowest reaction is considered as rate controlling step (Kapil *et al.*, 2011).

Langmuir-Hinshelwood-Hougen-Watson (LHHW)

In addition to assumption made in Langmuir model, Langmuir-Hinshelwood model assumed that both methanol and triglyceride are adsorbed on the adjacent active sites of catalyst. In the first two steps both methanol and triglyceride are adsorbed adjacently on the catalyst surface, subsequently, the adsorbed methanol (S.MOH) and triglyceride (S.T) resulted to S.FAME and adsorbed diglyceride. Consequently these adsorbed diglyceride (S.D) reacts with adsorbed methanol (S.MOH) to give fatty acid methyl esters (S.FAME) and adsorbed monoglyceride (S.D). Then adsorbed monoglyceride reacts with adsorbed methanol (S.MOH) to produce S.FAME and glycerol (S.G). Each of the following steps could be a rate controlling step. **Table 4**. shows the generalized rate equation for each elementary reaction (Kapil *et al.*, 2011).

Table 4 Kinetic rate equations for Langmuir- Hinshelwood-Hougen-Watson mechanism ($K=k_i/k_{-i}$)

Elementary reaction	Rate equation
$3S + 3MOH \leftrightarrow S.MOH$	$\frac{k_1 C_{MOH}^3 - K_{-1} \left(\frac{K_6 K_7 C_D C_{FAME}}{K_3 K_2 C_T} \right)^3}{\left(1 + \frac{K_6 K_7 C_D C_{FAME}}{K_3 K_2 C_T} + K_2 C_T + K_6 C_{FAME} + K_7 C_D + K_8 C_M + K_9 C_G \right)^3}$
$S + T \leftrightarrow S.T$	$\frac{k_2 C_T - K_{-2} \left(\frac{K_6 K_7 C_D C_{FAME}}{K_3 K_1 C_{MOH}} \right)}{\left(1 + K_1 C_{MOH} + \frac{K_6 K_7 C_D C_{FAME}}{K_3 K_1 C_{MOH}} + K_6 C_{FAME} + K_7 C_D + K_8 C_M + K_9 C_G \right)}$
$S.MOH + S.T \leftrightarrow S.FAME + S.D$	$\frac{k_3 C_{MOH} C_T - K_{-3} C_{FAME} C_D}{(1 + K_1 C_{MOH} + K_2 C_T + K_6 C_{FAME} + K_7 C_D + K_8 C_M + K_9 C_G)^2}$
$S.MeOH + S.D \leftrightarrow S.FAME + S.M$	$\frac{k_4 C_{MOH} C_D - K_{-4} C_{FAME} C_M}{(1 + K_1 C_{MOH} + K_2 C_T + K_6 C_{FAME} + K_7 C_D + K_8 C_M + K_9 C_G)^2}$
$S.MeOH + S.M \leftrightarrow S.FAME + S.G$	$\frac{k_5 C_{MOH} C_M - K_{-5} C_{FAME} C_G}{(1 + K_1 C_{MOH} + K_2 C_T + K_6 C_{FAME} + K_7 C_D + K_8 C_M + K_9 C_G)^2}$
$3S.FAME \leftrightarrow 3.S + 3 FAME$	$\frac{K_{-6} \left(\frac{K_1 K_2 K_3 C_{MOH} C_T}{K_7 C_D} \right)^3 - K_6 C_{FAME}^3}{\left(1 + K_1 C_{MOH} + K_2 C_T + \frac{K_1 K_2 K_3 C_{MOH} C_T}{K_7 C_D} + K_7 C_D + K_8 C_M + K_9 C_G \right)^3}$
$S.D \leftrightarrow S + D$	$\frac{K_{-7} \frac{K_1 K_2 K_3 C_{MOH} C_T}{K_6 C_{FAME}} - K_6 C_D}{\left(1 + K_1 C_{MOH} + K_2 C_T + K_6 C_{FAME} + \frac{K_1 K_2 K_3 C_{MOH} C_T}{K_6 C_{FAME}} + K_8 C_M + K_9 C_G \right)}$
$S.M \leftrightarrow S + M$	$\frac{K_{-8} \frac{K_6 K_9 C_{FAME} C_G}{K_5 C_{MOH}} - K_8 C_M}{\left(1 + K_1 C_{MOH} + K_2 C_T + K_6 C_{FAME} + K_7 C_D + \frac{K_6 K_9 C_{FAME} C_G}{K_5 C_{MOH}} + K_9 C_G \right)}$
$S.G \leftrightarrow S + G$	$\frac{K_{-9} \frac{K_1 K_5 K_8 C_{MOH} C_M}{K_6 C_{FAME}} - K_9 C_G}{\left(1 + K_1 C_{MOH} + K_2 C_T + K_6 C_{FAME} + K_7 C_D + K_8 C_M + \frac{K_1 K_5 K_8 C_{MOH} C_M}{K_6 C_{FAME}} \right)}$

Modified from Kapil, A., Wilson, K., Lee, A.F., Sadhukhan, J., 2011. Kinetic modeling studies of heterogeneously catalyzed biodiesel synthesis reactions. Industrial & Engineering Chemistry Research 50 (9), 4818–4830.

External Diffusion

In the case, when external diffusion of oil is the slowest step, then the rate equation can be calculated using the following equation (Fogler, 2005),

$$r = k(C_{TG_B} - C_{TG_S}) \quad (13)$$

Where, k is mass transfer coefficient, C_{TG_S} is concentration of TG on the surface, C_{TG_B} is concentration of TG on the bulk
The mass transfer co-efficient of TG in reaction mixture can be calculated using Frossling correlation

$$Sh = 2 + 0.6 \times Re^{1/2} \times Sc^{1/3} \quad (14)$$

Where,

$$Sh = \text{Sherwood number} = \frac{k d_p}{D_{AB}}$$

$$Re = \text{Reynolds number} = \frac{\rho d_p \omega D}{\mu}$$

$$Sc = \text{Schmidt number} = \frac{\mu}{\rho D_{AB}}$$

Where

d_p – Diameter of the particle (m)

ω – Angular velocity (rad/s)

ρ – Density (kg/m³)

μ – Viscosity (kg/m s)

D_{AB} – Diffusivity coefficient (m²/s)

Internal Diffusion

If the internal diffusion of TG is rate controlling step, the actual rate of reaction can be determined using Thiele modulus (ϕ_n^2)

$$\phi_n^2 = \frac{k_n \rho_c S_a C_{TGS}^{n-1} R^2}{D_e} = \frac{\text{surface reaction rate}}{\text{Diffusion rate}} \quad (15)$$

where,

k_n – Reaction rate constant for n^{th} order of reaction

ρ_c – Density of catalyst (kg/m^3)

S_a – Surface area of the catalyst per unit mass of catalyst (m^2/g)

C_{TGS} – Surface concentration of TG (kg/m^3)

R – radius of catalyst particle (m)

D_e – Effective diffusivity (m^2/s)

- (1) Small values of the Thiele modulus indicates that the surface reaction is controlled and a significant amount of the reactant diffuses well into the pellet interior without reacting.
- (2) Large values of the Thiele modulus indicates that the surface reaction is rapid and that the reactant is consumed very close to the external pellet surface with very little penetration into the interior of the pellet (Fogler, 2005).

Further, the actual reaction rate is calculated using the following equation

$$r = \frac{3}{\phi_n^2} (\phi_n \coth \phi_n - 1) k C_{AS}^n \quad (16)$$

C_{AS} can be calculated using the following equation

$$k_c (C_{A0} - C_{AS}) A_p = \eta k C_{AS}^n A_s \quad (17)$$

where,

k_c = mass transfer coefficient

$A_p = 4\pi R^2$

$A_s = S_a \cdot (\text{mass of the catalyst})$

Conclusion

Optimization studies on biodiesel production from non-edible jatropha oil using RSM was reported in this chapter. The application of RSM was highly useful for identifying the optimal levels of the selected factors and also it illuminates the interaction of each variable on the biodiesel production. Further, the kinetic models for homogeneous and heterogeneous catalyzed transesterification reaction was also discussed which would be helpful in designing a suitable reactor for biodiesel production.

Introduction

World Energy Scenario: Transportation Sector

Energy consumption is an indicator of economic growth and standard of living in any civilization. After the Industrial Revolution in the late 18th and early 19th century, the energy consumption of the world has increased exponentially over the years. According to the prediction in a U.S. Energy Information Administration (2017) report, the total energy consumption of the world will increase from 575 quadrillion British thermal units (Btu) in 2015 to 663 quadrillion Btu by 2030 and then to 736 quadrillion Btu by 2040. Thus, the world will need around 30% more energy in 2040 compared with 2015. Most global primary energy is produced from the conventional energy sources (fossil fuels). As shown in Fig. 1, oil, coal, and gas remain the dominant resources with 86% contribution of total world energy, while hydro, nuclear, and other renewable energy account for 7%, 4%, and 3% of the total primary energy consumption, respectively (British Petroleum Company, 2017). The transport sector, which includes automobiles, ships, trains, and airplanes, is the second largest global energy consumer after the industrial sector (Fig. 2). This sector accounts for 25% of world's total energy consumption, of which 80% is used for road transport (U.S. Energy Information Administration, 2017). Around the world, the vehicle fleet (both commercial vehicles and passenger cars) is growing rapidly. There were about 1.1 billion total global vehicles on the road in 2013 and this is projected to be around 2.3 billion (which is more than double) by 2035. In India and China, projected vehicle density per 1000 population is expected to grow from 20 to 130 (8.4% p.a.) and 80 to 360 (6.9% p.a.),

Fig. 1 Global primary energy production in 2015. Source: British Petroleum Company, 2017. BP Energy Outlook 2017. Retrieved from <https://www.bp.com/content/dam/bp/pdf/energy-economics/energy-outlook-2017/bp-energy-outlook-2017.pdf>.

Fig. 2 Global primary energy consumption. Source: U.S. Energy Information Administration, 2017. International Energy Outlook 2017. International Energy Outlook (vol. IE02017). respectively, between 2012 and 2035 (British Petroleum Company, 2014). The transport sector is currently consuming around 60% of world oil demand and will be the largest growing energy sector in the coming days. This sector consumes nearly all conventional fuel energy that comes from oil (97.6%) and a small amount from natural gas (Atabani *et al.*, 2012). But transport demand for oil is decelerating with significant improvement of fuel efficiency and increase in use of nonoil fuels (electricity), biofuels, coal, and natural gas. Total oil demand for this sector is expected to fall gradually from about 1 Mb/d p.a. in 2015 to about 0.4 Mb/d p.a. by 2035 (British Petroleum Company, 2017).

World Emission Problem

Climate change is currently the most irresistible world environmental problem. If world's average temperature increases by 2°C from the preindustrial revolution era, more than one million species may become extinct and hundreds of millions of humans may lose their lives (Atabani *et al.*, 2012).

Environmental scientists have noticed that carbon dioxide (CO₂) concentration in the Earth's atmosphere has been increasing significantly over the past century. The average concentration of CO₂ was 399 parts per million (ppm) in 2015, which was about 40% higher than in the mid-1800s (280 ppm). The average growth of CO₂ was 2 ppm/year over the last ten years (IEA, 2016). It is expected that about 6.2 billion metric tons of carbon dioxide will be released into the atmosphere between 2015 and 2035 (EIA, 2017). The levels of methane (CH₄) and the oxides of nitrogen (NO_x) have also increased significantly. Electric utility sector (42%) and transport sector (23%) together produced two-thirds of global CO₂ emissions from fossil fuel combustion in 2014 (Fig. 3) (IEA, 2016). In 2014, three-quarters of the transport sector emission was driven from the road sector, which was increased by 71% since 1990 (Fig. 4). About 95% greenhouse gas (GHG) emission from transportation is of CO₂ and only 1% is of methane (CH₄) and nitrous oxides (N₂O). The transportation sector also emits carbon monoxide (CO), ozone, and hydro fluorocarbons (HFCs) from the cooling system of the vehicles (Atabani *et al.*, 2012). Such a fast growth of emissions will directly affect the stable ecosystem and thus the global climate. In this context, the renewable and nonconventional fuels, such as biofuel, biogas, and biodiesel, can be used as alternative sources of energy. So, there is a growing need to focus on developing suitable biofuels to reduce the dependency on fossil fuels.

Biodiesel as an Emerging Energy Resource

The biofuels, mainly produced from biological resources, are available in both liquid and gaseous states for transportation purposes. Various types of fuels can be produced from bioresources, which include liquid fuels, such as bioethanol, biomethanol, biodiesel, and gaseous fuels, such as producer gas and biogas. Among all these fuels, biodiesel is one of the most reliable options as an alternative to the base fuel, diesel. It is highly biodegradable, has lower sulfur content, lower aromatic content, and minimal toxicity (Balat and Balat, 2010). Biodiesel has higher cetane number (CN) and higher flash point (FP), which offers safety benefits over diesel fuel (Demirbas and Balat, 2006). It generally contains 10%–11% oxygen by weight, which improves combustion efficiency and also minimizes CO and unburned hydrocarbon emissions (Atabani *et al.*, 2012). It produces no net carbon dioxide (if the whole life cycle of the tree is considered) and less particulate matter (PM) and smoke (Atabani *et al.*, 2012). Therefore, biodiesel–diesel blends can be used as fuel in internal combustion engines without major modifications.

Biodiesel is commercially available in many countries such as the United States, Brazil, Germany, Argentina, France, Thailand, and various European countries (Sawin *et al.*, 2017). Fig. 5 shows the amount of biodiesel production in 2016 of some of the top biodiesel producing countries, and shows that the United States was the highest biodiesel producer, with 5.5 billion liters, in 2016. Worldwide annual biodiesel production increased from 7 billion liters in 2006 to 31 billion liters in 2016 (Sawin *et al.*, 2017). In the last decade, the growth rate of biodiesel production was around 35% per annum. Therefore, biodiesel has a massive capability to be a part of sustainable energy source in the future.

Biodiesel Production Potential: Feedstock and Availability

The use of vegetable oil in an engine is not a new idea and the concept of using vegetable oil as fuel dates back to 1895. In fact, when Rudolph Diesel developed the first engine in 1900, he ran it on peanut oil (Srithar *et al.*, 2013). However, vegetable oil has several drawbacks as engine fuel, the major of which are its very high viscosity and pour point (PP), low calorific value (CV), and low volatility (Rakopoulos, 2013). The highly viscous vegetable oil leads to difficulty in pumping, causes poor atomization, and also poor combustion in a diesel engine. This can be improved by preheating the oil, blending it with a base fuel, and transesterification or pyrolysis. The most popular method of decreasing the viscosity of vegetable oil is transesterification (Prabhu *et al.*, 2013; Prakash *et al.*, 2013; Sivalakshmi and Balusamy, 2013). Transesterification (also called alcoholysis) is the displacement of alcohol from an ester by another alcohol (Meher *et al.*, 2006). The transesterification reaction is represented by the general equation [Eq. (1)] as follows:

It is a reversible reaction and proceeds essentially by mixing the reactants. However, the presence of a catalyst (a strong acid or base) accelerates the conversion process. Transesterification of triglycerides (as found in vegetable oils) produces fatty acid (FA) alkyl esters and glycerol. The heavier glycerol layer settles down at the bottom of the reaction vessel. The upper layer of (m)ethyl ester forms the raw biodiesel. Diglycerides and monoglycerides are the intermediates in this process. The mechanism of transesterification is described in Eq. (2) (Sivakumar *et al.*, 2015), where R^i represents a mixture of various FA chains. The major components of vegetable oils and animal fats are triacylglycerols or, in short, triglycerides. The triglycerides of oils or fats primarily contain several different FAs, which can be attached to one glycerol backbone. The vegetable oil or animal fat is reacted in the

Fig. 5 Leading biodiesel producers worldwide in 2016, by country. Source: Sawin, J., Seyboth, K., Sverrisson, F., 2017. Renewables 2017 Global Status Report. Retrieved from http://www.ren21.net/wp-content/uploads/2017/06/17-8399_GSR_2017_Full_Report_0621_Opt.pdf.

presence of a catalyst (usually a base) with alcohol (usually methanol) to give the corresponding alkyl esters (or for methanol, the methyl esters) of the FA mixture that is found in the parent vegetable oil or animal fat. This alkyl ester is known as biodiesel.

Acid-Catalyzed Pretreatment

If the oil or fat contains significant amounts of free fatty acid (FFA), acid-catalyzed pretreatment process is required. Usually, nonedible oil or animal fat contains 2%–30% FFA (Knothe *et al.*, 2010). The high FFA feedstock reacts with the alkali catalyst and generates soap and water as shown in the reaction [Eq. (3)] below:

In general, the reaction is catalyzed with an alkali catalyst for less than 2% FFA in oil or fat, but up to ~ 5% FFA can be possible to complete reaction in the presence of alkali catalyst (Knothe *et al.*, 2010). When the FFA level is > 5%, the soap resists the separation of glycerol from alkyl ester and emulsion formation take place during water wash. For these cases, an acid catalyst (such as H_2SO_4) is used to esterify the FFA to alkyl ester. The reaction is shown in Eq. (4).

This process is normally used as a pretreatment to convert the FFA to methyl esters, thereafter the alkaline transesterification is applied to produce biodiesel. The complete biodiesel production process is shown in Fig. 6.

Biodiesel Resources

The selection of vegetable oil used in transesterification for the production of biodiesel varies from region to region, depending upon the climate and soil conditions (Karmakar *et al.*, 2012). For example, in the United States soybean oil is widely used for the preparation of biodiesel, while in Europe rapeseed and sunflower oils are more popular for the same. Similarly, palm oil is used in southeast Asia, coconut oil in the Philippines, animal fat in Japan, and canola oil in Canada (Murugesan *et al.*, 2009; Karmakar *et al.*, 2012).

In general, biodiesel feedstock can be divided into four types (Kumar *et al.*, 2013):

- (1) *Edible vegetable oil*: Rapeseed, soybean, sunflower, rice bran, coconut, palm, corn, olive, sesame seed, palestine, peanut, safflower oil etc.
- (2) *Non-edible vegetable oil*: Neem, mahua, jatropha, pongamia, jojoba, cottonseed, orange, linseed, kusum, sea mango, halo-phytes, algae etc.
- (3) *Animal fats*: Chicken fat, tallow, yellow grease and fish oil (from byproducts), etc.
- (4) *Waste cooking or recycled oil*.

Fig. 6 The flowchart of biodiesel production process.

Table 1 Maximum allowed quantities of physicochemical properties for diesel and biodiesel according to ASTM/EN standards

Property	Unit	Diesel	Biodiesel	
		ASTM D975	ASTM D6751	EN 14214
Density at 15°C	kg/m ³	850	Max. 880	860–900
Kinematic viscosity at 40°C	mm ² /s	2.0–4.5	1.9–6.0	3.5–5.0
Cetane number	–	40–55	Min. 47	Min. 51
Iodine value	mg I ₂ /g	–	–	Max. 120
Calorific value	MJ/kg	42–46	–	Min. 35
Acid number	mg KOH/g	–	Max. 0.5	Max. 0.5
Pour point	°C	–15 to 5	–15 to –16	–
Flash point	°C	60–80	Min. 100–170	> 120
Cloud point	°C	–35 to 15	–3 to –12	–
Cold filter plugging point	°C	–25	19	Max. 5
Copper strip corrosion (3 h at 50°C)	–	1	Max. 3	–
Carbon	wt%	84–87	77	–
Hydrogen	wt%	12–16	12	–
Oxygen	wt%	0–0.31	11	–
Sulfur content	%(m/m)	0.05	Max. 0.05	–
Sulfate ash content	%(w/w)	0.01	0.02	0.02
Oxidation stability at 110°C	h	–	Min. 3	Min. 6
Lubricity	–	685	314	–

Note: Dharma, S., Ong, H.C., Masjuki, H.H., Sebayang, A.H., Silitonga, A.S., 2016. An overview of engine durability and compatibility using biodiesel–bioethanol–diesel blends in compression-ignition engines. *Energy Conversion and Management* 128, 66–81.

Characteristics of Biodiesel

Biodiesel is one of the best alternatives to diesel and can be used as alternative fuel in compression ignition (CI) engines. The engine injection, combustion, performance, and emission characteristics are influenced by biodiesel properties, which depend on the FA compositions and types of feed stocks (Dharma *et al.*, 2016; Sakthivel *et al.*, 2017). In many countries, biodiesel has been successfully introduced and commercialized. Hence, some biodiesel standards, like ASTM D6751 and the European standard EN 14214, have been developed to certify high product quality and to improve user confidence. The biodiesel is characterized by determining its different physicochemical properties like density, viscosity, FP, cloud point (CP), pure point, CV, volatility, etc. ASTM and EN standards of maximum allowed quantities of different properties for diesel and biodiesel are shown in Table 1. The important properties of different biodiesels are given in Table 2.

Density

Density is an important property for liquid fuels used in engines. This is because the liquid fuels are generally sold in volume quantity while their heating values are expressed on a gravimetric basis. Therefore, the heat content in a certain volume of diesel depends on its density. There is evidence showing that the ignition delay in diesel engine is sensitive towards the density of the fuel (Ra *et al.*, 2008). Measurement of density follows the ASTM Standard D1298 and EN 3675 test methods (Zaharin *et al.*, 2017). Table 2 indicates that biodiesel density is higher compared with base fuel diesel as the molecular weight of biodiesel is higher (Zaharin *et al.*, 2017). It can be clearly seen that density of most of the biodiesels lie in the range of 850 kg/m³ to 930 kg/m³. Among them, biodiesel from jatropha has the minimum density value around 857 kg/m³ whereas castor oil biodiesel shows the maximum with 928.7 kg/m³.

Kinematic Viscosity

Kinematic viscosity is an important property of fuel, which directly influences the fuel atomization quality and size of the fuel droplet in the spray. In general, kinematic viscosity is measured using the ASTM Standard D445 and EN 3104 test methods. Low viscous fuel may lead to leakage in the fuel system and high viscosity may disturb the fuel flow rate during intake stroke, which delays the mixing of air and fuel in the combustion chamber (Dharma *et al.*, 2016). Kinematic viscosity for most of the biodiesels ranges between 3 mm²/s and 5.5 mm²/s at 40°C, but for castor oil biodiesel it is exceptionally high (16.67 mm²/s).

Cetane Number

CN indicates the knocking tendency of diesel in a CI engine. High CN fuel tends to ignite early in the engine cylinder, which decreases the knocking tendency of the engine. The CN depends on the presence of saturated molecules and the length of FA carbon chains in the

Table 2 Physiochemical properties of different biodiesels

Fuels	Density (kg/m ³)	Kinematic viscosity (40 °C) (mm ² /s)	Cetane number	Calorific value (MJ/kg)	Cold filter plugging point (°C)	Flash point (°C)	Carbon content (wt%)	Hydrogen content (wt%)	Oxygen content (wt%)	Surface tension (40°C) (mN/m)

fuel (Zaharin *et al.*, 2017; Sakthivel *et al.*, 2017). High CN fuels provide significant advantages in terms of engine performance and emission characteristics, which allow the engine to run smoothly with less tendency of knocking and noise disturbance (Zaharin *et al.*, 2017). The CN of biodiesel fuel is measured by ASTM D613 and EN 5165 test methods. Table 2 shows that most of the biodiesels have higher CN than base fuel diesel. It may be due to the presence of long FA carbon chains in the biodiesel (Ashraful *et al.*, 2014).

Calorific Value

CV denotes the energy content in a fuel. High calorific value of fuel is the most desirable as releasing more heat during combustion improves the engine power output (Hasan and Rahman, 2017). CV of biodiesel has been prescribed in EN 14213 standards with a minimum value of 35 MJ/kg. Biodiesels usually have lower CV than diesel fuel (see Table 2) because of the higher oxygen content in them (Ashraful *et al.*, 2014).

Cloud Point and Pour Point

The information regarding CP and PP of fuels is essential for low temperature operation of the engine. The CP is the temperature at which a cloud of wax crystals first becomes visible when the fuel is cooled. The PP of a fuel is the temperature below which the fuel loses its flow characteristics. CP and PP are measured following ASTM D2500 and D97 standards. In general, these two points for biodiesels are higher than the base fuel diesel (Atabani *et al.*, 2013). Cold filter plugging point (CFPP) is used as an indicator of low temperature operability of fuels. At this temperature, the test filter starts to plug due to gel formation or crystallization of fuel components. Usually, the CFPP of a fuel is lower than its CP. The CFPP is measured by ASTM D6371 standard. It has been found from Table 2 that the highest CFPP is found for animal fat oil biodiesel with temperature of 10°C while karanja oil biodiesel has the lowest CFPP temperature of −2°C.

Flash Point

FP is another important property for a liquid fuel. FP is defined as the temperature at which the fuel flashes when exposed to a flame or a spark. FP varies inversely with the fuel's volatility. FP is measured according to ASTM D93 and EN ISO 3679 standard. Biodiesel has a high FP, which is normally more than 150°C, while generally diesel fuel has a flash point of 55–66°C (Atabani *et al.*, 2013).

Elemental Analysis

Using elemental analyzer, the composition of fuel is measured according to ASTM D3176 standard, which is a measure of carbon, hydrogen, nitrogen, sulfur, and oxygen content in a fuel. The main components of diesel are carbon and hydrogen but no oxygen, whereas biodiesels have generally 10–15 (wt%) oxygen ([Table 2](#)).

Surface Tension

Surface tension is also an important fuel property, which affects the characteristics of the spray issued from a fuel nozzle. Higher surface tension value of a fuel results in coarser droplets in the spray ([Das et al., 2018a](#)) because of the increase in the cohesive force, resisting disintegration. The surface tension of fuel is measured following ASTM D971 standard. Generally, biodiesel has higher surface tension than conventional diesel fuel ([Table 2](#)). Higher molecular weight and unsaturation in the molecular structure of the biodiesel increases the viscosity and surface tension of biodiesel compared with diesel.

Engine Performance and Emission Characteristics

The performance and emission characteristics of a diesel engine mainly depend on fuel properties and the engine operating variables such as compression ratio, injection pressure, ignition delay, and other factors. The biodiesel–diesel blend can be directly used in a CI engine. The effect of the biodiesel on an engine can be investigated by the analysis of the engine performance characteristics like brake thermal efficiency (BTE), brake specific fuel consumption (BSFC), and emission parameters such as CO, carbon dioxide (CO₂), unburnt hydrocarbon (HC), smoke, and NO_x. In the following sections, a detailed discussion has been carried out on the performance and emission parameters of various biodiesel–diesel blends.

Brake Thermal Efficiency

BTE is defined as the ratio of the useful work obtained by an engine to the fuel energy supplied to the engine. Most of studies reported higher BTE for biodiesel–diesel blends related to base diesel fuel ([Table 3](#)). [Teoh et al. \(2014\)](#) reported 2% higher BTE for B50 (jatropha biodiesel) compared with mineral diesel. Researchers suggested that oxygen content of the biodiesel enhanced the burning rate during the combustion. [Mathimani et al. \(2017\)](#) also found better BTE for B30, B40, and B50 of *Chlorella vulgaris* BDUG 91771 biodiesel–diesel. It was due to shorter ignition delay of the biodiesel. [Rakopoulos et al. \(2008\)](#) ran a Mercedes-Benz minibus diesel engine using biodiesel of sunflower and cottonseed oil and their blends with diesel. BTE of blends of these two biodiesels was similar to the base fuel diesel. [Das et al. \(2018b\)](#) was also obtained similar or slightly higher BTE for castor oil biodiesel–diesel blends (B05, B10, and B20). On the other hand, BTE was reduced up to 4.2% with 20% blend of canola biodiesel at higher load as the calorific value of the biodiesel was 9.6% less than diesel ([Can et al., 2017](#)). [Santhosh and Padmanaban \(2016\)](#)

Table 3 Comparative changes of engine performance and emission parameters for biodiesel blends with respect to diesel

Feed stock of biodiesel	Performance		Emission				Reference
	BSFC	BTE	CO	HC	Smoke	NO _x	
Sunflower oil (B10, B20) Cottonseed oil (B10, B20)	Increase	Similar	Decrease	Slightly increase	Decrease	Slightly increase	(Rakopoulos et al., 2008)
Jatropha oil (B10, B30, B50)	Increase, ↑6% (B50)	Slightly reduced ↑2% (B50)	Decrease ↓11.9, 30, 49.9%	–	Decrease ↓20.9 (B10), 69.5 (B50)	Decrease ↓20.2% (B30)	
<i>Citrullus colocynthis</i> L. oil (B30, B100)	↓B30↑B100	Increase	–	↓20 (B30), 50 (B100)	Decrease, ↓22%	Increase	(Alloune et al., 2018)
Algal oil (<i>Chlorella vulgaris</i> BDUG 91771) B30, B40, B50, B60	Increase	↑B30, B40, B50 ↓B50	Decrease	Decrease	–	Marginally lower or equal	(Mathimani et al., 2017)
Canola oil (B05, B10, B15, B20)	↑up to 6.56%	↓ up to 4.2%	↓32% (max)	↓30.3% (max)	↓24.5 (ML), 53.5 (FL) for B20	↑3%–9%	(Can et al., 2017)
Sal oil (B10, B20, B30, B40)	↓1.84 % (B10), 2.09% (B20) at 80% load, ↑< B20	↑2.3 % (B10), 2.4% (B20) at 80% load, ↓< B20	↓at full load	Decrease	↑ at 0%–40% load, ↓50% at 90% load	Increase	(Pali and Kumar, 2016)
Cottonseed oil (B15, B30, B45, B60, B75, B90, and B100)	Increase	↑for lower blends	↓B15–B60	Decrease	Decrease	Increase	(Santhosh and Padmanaban, 2016)
Rapeseed oil (B5, B20, B70, B100)	↑2.5%, 3%, 5.5%, 7.5%	Decrease	Decrease	Decrease	Decrease, ↓45% for B70	Increase	(Buyukkaya, 2010)
Soya bean oil (B30, B50, B80, B100)	Increase	Decrease	Decrease, ↓0.05%	Decrease	Decrease	Increase	(Qi et al., 2010)

investigated that at high compression ratio (22.1:1), BTE could be improved using lower percentage blends of cottonseed biodiesel and diesel. This was due to the better spray characteristics in the lower biodiesel–diesel blends and hence better combustion.

Brake Specific Fuel Consumption

BSFC is defined as the ratio of the total fuel consumption rate to the brake power output of the engine. It is one of the most important parameters for evaluating the effects of fuels on an engine performance. Generally, higher BTE outcomes in lower BSFC and lower calorific value of fuel enhance the BSFC. Most researchers (Table 3) reported that BSFC increased when biodiesel–diesel blends were used as fuels in the engine. When the engine is fueled with 50% blend (B50) of jatropha biodiesel and diesel, Teoh *et al.* (2014) observed that the engine consumed more B50 fuel compared with mineral diesel for same power output. This was because of the lower calorific value of the biodiesel, approximately 6% less than that of diesel fuel. The higher specific fuel consumption (SFC) was obtained with increase of the cottonseed biodiesel concentration in the blend (Santhosh and Padmanaban, 2016). The percentage increment in SFC for B15, B30, B45, B60, B90, and B100 were 4.06%, 0.41%, 4.54%, 8.19%, 8.76%, 14.76%, and 16.71%, respectively, at medium load. 30% blend (B30) of the *Citrullus colocynthis* L. biodiesel and diesel reduced BSFC compared with diesel as higher CN with lower viscosity of B30 fuel (Alloune *et al.*, 2018). Pali and Kumar (2016) observed that for up to 20% blend of sal oil biodiesel, BSFC was reduced about 2% compared with diesel. However, BSFC was enhanced for more than 20% blends.

Carbon Monoxide

CO, an intermediate combustion byproduct of burning fuels, is produced by different factors like absence of oxidant, non-uniformly mixing of air–fuel mixture, lack of time for postoxidation, etc. (Sakthivel *et al.*, 2017). In Table 3, we observe that most studies found lower CO emission in an engine fueled with biodiesel or its blends. Many researchers suggested that this was mainly due to the oxygen content in biodiesel enhancing to complete combustion of the fuel. CO emission was decreased with the use of jatropha oil methyl ester (biodiesel) in the blend and in fact, it consistently reduced with the increase of biodiesel proportion in the blend (Teoh *et al.*, 2014). Buyukkaya (2010) noticed that CO emission was reduced at low engine speed for rapeseed oil biodiesel–diesel blended fuel. The CO emissions of the B5, B20, B70, and B100 were 12%, 25%, 31%, and 35%, respectively, lower than that of diesel fuel.

Hydrocarbon

HC emissions indicate the incomplete combustion of fuel inside the combustion chamber of an engine. Combustion chamber construction, engine operational conditions, fuel type or structure are the main constraints that influence on the HC emissions (Sakthivel *et al.*, 2017). The Table 3 conclusively shows that HC emissions from engines with the use of biodiesel or its blends are lower than baseline diesel. Alloune *et al.* (2018) found that the reduction of HC emissions was obtained for pure *C. colocynthis* L. biodiesel and its 30% blend compared with diesel fuel. This was due to the presence of oxygen in biodiesel, which improved combustion quality of the fuel. Authors explained furthermore that the higher CN of biodiesel and its blend reduced the ignition delay, and as a result, had a substantial effect on the lower HC emission. Rakopoulos *et al.* (2008) observed that HC emissions from B10 and B20 blend (sunflower or cottonseed biodiesel–diesel) fueled Mercedes-Benz, minibus diesel engine were slightly higher than that of diesel fuel.

Oxides of Nitrogen

Formation of NO_x, the most toxic pollutants, in CI engines is dependent on in-cylinder peak temperature, type of the fuels, oxygen availability in the high temperature zones, and reaction time. In biodiesel–diesel blends, different parameters such as chemical composition of the fuel and concentration of oxygen in the high temperature reaction zone are changed, which may directly affect NO_x emission (Agarwal *et al.*, 2017). Pali and Kumar (2016) found higher NO_x with the use of sal oil biodiesel and its blends as compared with diesel fuel. They suggested that higher combustion temperature and excess oxygen were the predominant factor for higher NO_x emissions. In the case of pure rapeseed biodiesel, the enhance of NO_x emission was about 12% compared with the base fuel (Buyukkaya, 2010). Similarly, 6% and 9% higher NO_x emissions were found for B20 and B70, respectively. Mathimani *et al.* (2017) noticed that NO_x emissions from all algal biodiesel blends fueled engine were slightly lower or equal to the corresponding base fuel at all loads. This was due to the shorter ignition delay and lower exhaust gas temperature.

Smoke and Particulate Matter

Smoke and PM are the unwanted byproducts of combustion in a diesel engine, and are primarily produced from incomplete combustion of fuel. The formation of smoke or PM mostly depends on the type of fuels, operating conditions of the engine, and carbon residue of the fuel (Teoh *et al.*, 2014). Pali and Kumar (2016) observed that smoke opacities for sal oil biodiesel and its blends were higher at part loads (up to 40%). This was because of higher viscosity of the biodiesel and lower in-cylinder

temperatures at these low loads, leading to poorer spray along with locally rich fuel mixtures and generating more smoke. However, smoke was significantly reduced at higher loads. PM emission from pure algal oil biodiesel fueled engine was lower than that of diesel fuel, as the biodiesel supplied extra amount of oxygen in the premixed reaction zone and reducing PM emission (Alloune *et al.*, 2018). The reduction of PMs for the biodiesel is about 22% as compared with base fuel. However, B30 and diesel generated the same amount of PM.

Conclusion

With recent increase in prices of crude petroleum-based fuels and uncertainties of the availability of these fossil fuels, there is renewed interest in alternative ecofriendly and easily available fuels. Biodiesel is the most promising alternative to the fossil diesel fuel. Biodiesel can be produced from any type of vegetable oils, animal oil/fats, tallow, and waste cooking oil. Transesterification is the most popular method to produce biodiesel from different feedstocks. Biodiesel or its blends can be directly used in existing CI engines without any modification or with minor modification, mainly compression ratio, fuel injection timing or exhaust gas recirculation, etc. In general, the BTE of an engine with the use of biodiesel–diesel blends is similar or slightly reduced (about 4%) as compared with mineral diesel. On the other hand, BSFC is normally increased for biodiesel–diesel blends. All types of emissions except nitrogen oxides are significantly decreased (about 20%–50%) by using biodiesel or its blend as fuel instead of base diesel fuel. Finally, biodiesel has emerged as an alternative environment-friendly fuel, which can be partially mixed with diesel and easily used in existing engines with great reduction of pollution but with minor loss in power output.

Introduction

Cork is a natural additive combining to different binders presents composites of a very good thermal performance, using in building it reduces a lot the energy consumption due to the energy necessary of heating or cooling in summer. Authors in this work try to present the different performance of cork, to describe the characteristics of the materials cement mortar, clay and white cement used to produce the composites clay-cork, cement mortar-cork and white cement-cork. Two kinds of studies were done: the variation of the size of cork and its volume fraction to show the influence of the form of cork and the volume fraction on thermal properties of the composites produces. Thermal characterization of materials: clay, cement-mortar and white cement combining with this additive were done using the hot plate and flash methods in both regimes under steady state and transient conditions. The physical–chemical description of cork was done.

Molina *et al.* (2018) studied the fire response and flammability of cork using bench and field scales. The paper treats the oak tree cork flammability using a set comprised of 120 cork specimens and 120 cork pieces to test the cambial temperature and lethal temperature rate according to cork bark roughness, cork thickness, cork porosity and cork quality and results reveal that those characteristics influence the vulnerability of cork oak forests to wildfires and a thickness of over than 3.7 cm prevented reaching lethal cambial temperature.

Sarasini *et al.* (2019) studied the impact of green sandwich structures made of agglomerated cork encapsulated between two thin flaxes/epoxy face sheets compared to a traditional synthetic foam core, the results reveal that the cork based structures exhibited a higher perforation threshold than foam sandwiches (94.41 J instead of 79.71 J) for the foam synthetic core.

Kaczynski *et al.* (2019) assessed the capability of five different types of cork agglomerates to withstand 500 J impact according to different temperature conditions, the results indicate that the capability of absorbing energy depends on the density of cork and the temperature, the grain size of cork influence the value of absorbed energy, a mathematical cork agglomerated model for energy absorption was formulated and the cork agglomerates performance is significantly affected by the temperature.

Tártaro *et al.* (2017) calculated the carbon footprint of insulating cork board following the life cycle thinking approach and the ISO/TS 14067. The authors have compared the carbon footprint of the insulating cork board to other insulating material such as the expanded polystyrene ($59 \text{ kgCO}_2 \text{ m}^{-3} \text{ ICB}^{-1}$), the extruded polystyrene ($94.4 \text{ kgCO}_2 \text{ m}^{-3} \text{ ICB}^{-1}$), the polyurethane ($127.7 \text{ kgCO}_2 \text{ m}^{-3} \text{ ICB}^{-1}$), the stone wool ($34.35 \text{ kgCO}_2 \text{ m}^{-3} \text{ ICB}^{-1}$), the lightweight expanded clay aggregates ($53.77 \text{ kgCO}_2 \text{ m}^{-3} \text{ ICB}^{-1}$), However the ICB present a negative carbon footprint of $-116.229 (53.77 \text{ kgCO}_2 \text{ m}^{-3} \text{ ICB}^{-1})$.

Şen *et al.* (2014) treated the role of chemical components on the thermal degradation of cork using coupled differential scanning calorimetry-thermogravimetical analysis. The thermal decomposition of corks and phloem occurred at temperature above 200°C and increased at higher temperatures until about 485°C where the material becomes ash. The Fig. 1 of thermogravimetical analysis of the untreated Q.cerris and Q.suber corks showed quite a similar thermal degradation, however TGA curve of phloem differs from cork, mass loss below 250°C is higher than corks due to the higher percentage of polysaccharide content in phloem.

Physical–Chemical Characterization of Cork

The cork is known by its low density, high compressive characteristics, high elasticity, high adherence and high impermeability properties.

Fig. 1 Granular cork.

Fig. 2 Transversal section of oak cork trunk.

Cork is the parenchyma Suber created by the meristem suberophelo-dermic oak cork as shown in [Fig. 1](#).

Taxonomy of Oak Cork

The taxonomy of oak tree is described as below:

- Species; Suber L
- Kind: Quercus
- Family: Fagaceae
- Order: Fagale
- Class: Dicotyledonous
- Under branch lines: Angiosperm
- Branch: spermatophyte

Biology of Oak Cork

This tree essence can survive for 300 years. It is mainly calcifuge and siliceous and does not support cold. [Fig. 2](#) describes the different part of an oak cork trunk which consists of the bark of cork, the phellogen layer, the liberou, the cambium and finally the wood.

[Fig. 3](#) shows the microstructure of cork which seems to be like cells, things which prove the best properties in term of impermeability to gases and liquids, lightness, thermal and acoustic insulations.

Properties of Expanded Granular Cork

[Table 1](#) shows the thermal, the acoustic and the ant vibration characteristics of expanded granular cork in term of density, thermal conductivity and flexure strength. Acoustic expanded granular cork has the light and the most insulating characteristics but it possesses a low mechanical characteristic of low flexure strength. However, the ant vibration expanded cork possesses the low thermal properties and the high mechanical characteristics. This table gives an idea about the different kind of expanded granular cork and their characteristics according to the utilization.

Fig. 3 Scanning electron microscopic analysis of structure of cork which is a honeycomb.

Table 1 Characteristic of expanded granular cork

Kind of expanded granular cork	Density (kg m^{-3})	Thermal conductivity ($\text{W m}^{-1} \text{K}^{-1}$)	Flexure strength (MPa)
Acoustic	80–100	0.037	1.4–1.6
Thermal	100–130	0.039	1.4–2
Antivibration	175–190	0.048	2.7–3.2

Fig. 5 Composites cement mortar-cork at different sizes of cork.

Composites Cork Joints

The composites studied in this work are: (i) clay-cork, (ii) cement mortar-cork, and (iii) white cement-cork. **Fig. 4(a)–(d)** shows composite clay cork with various fractions of cork. **Fig. 5(a)–(c)** shows composite cement mortar-cork with various sizes of cork. **Fig. 6(a)–(c)** shows white cement-cork with various sizes of cork

Preparation of Samples

Cement mortar cork

The procedure of preparing samples of cement mortar-cork (MC-co) and cement mortar (MC) is described in this paragraph. A mold of dimensions $100 \times 100 \times 20 \text{ mm}^3$ was filled with cork until it was full. Then the volume of mold filled entirely by cork was considered as the 100% of cork's size (5–6.3 mm, 6.3–8 mm, 8–12.5 mm). The cement mortar was then added in a manner such that it fills in all the void existing between the grains of cork. At the same time samples of cement mortar alone were prepared to

Fig. 6 Composites white cement-cork with different sizes of cork. Reproduced from Cherki, A., Khabbazi, A., Mounir, S., Maaloufa, Y., 2014. Thermal properties of a new ecological building material/granular cork embedded in white cement. In: Proceedings of the MATEC Web of Conferences 11, p. 01017. doi:10.1051/mateconf/20141101017.

compare the thermal properties of the composites cement mortar-cork and cement mortar alone (50% cement-50% sand and 0.5 ratio of water per binder). After these all samples were put in a stove to remove the moisture from it. Finally samples were preserved in plastic bags to prevent it from absorbing moisture.

Knowing the densities of each material, mortar cement and granular cork and that of the mixture and depending on the law of mixture, the granular cork volume fraction was deduced for each sample of the composite material according to the formula given in Eq. (1). The volume fraction is:

$$\gamma = \frac{\rho_{c+co} - \rho_c}{\rho_{co} + \rho_c} \quad (1)$$

where, ρ_{c+co} is the apparent density of the composite binder-cork, ρ_c is the apparent density of the binder and ρ_{co} is the apparent density of the cork.

White cement cork

The samples were fabricated in a mold of dimensions $100 \times 100 \times 20 \text{ mm}^3$ in which, different sizes of cork (a) 5–6.3 mm, (b) 6.3–8 mm, (c) 8–12.5 mm were filled up to 100% mold volume and then the space between grains were filled by the white cement. Also samples of white cement were prepared at a ratio of water to binder equal to 0.5. Finally, all samples were put in a stove and weighing their masses each time until it became constant.

Clay cork

The study of the composites clay-cork was treated differently from the composites of cement mortar-cork and white cement-cork. To see the effect of the variation of the volume fraction in the binder, the mold dimensions ($100 \times 100 \times 20 \text{ mm}^3$) was filled with granular cork of size 6.3–8 mm. After it was totally full, the mass was considered 100% volumes of cork and the mass equal to 80% and 60% were calculated. Then the voids were filled with clay with a ratio of water to binder of 0.5. Also samples of clay alone were prepared to compare both samples (with and without cork). Then all samples were put in a stove to remove the moisture from the samples. Mass was controlled regularly until it became constant. Apparent density was measured according to the formula given by Eq. (1).

Description of the Used Materials

Cement mortar

The cement used was CPJ45 in accordance with the norms NM 10.1.004. The proportion of cement on the mortar was 50%. The percentage of water in binder (W/g) used was 0.5. The sand was taken according to the proportion of sand on the mortar as 50%. The fineness modulus of used sand was 2.15. The absolute density was 2.65 g cm^{-3} , the intergranular porosity was 46.58% and the equivalent sand was 92.3%.

White cement

The white cement used was the CEM II A-I-42.5N according to the norms NF EN197-1 and NFP 15-318 was used according to the NM 10.1.004. The percentage of water in the binder (W/g) used was 0.5.

Clay

The chemical composition of is given in Table 2.

Description of the Thermal Characterization Methods

The asymmetrical hot plate (Mounir *et al.*, 2019; Yves, 2011) was used to determine thermal conductivity and thermal effusivity under steady state and transient conditions. Flash (Degiovanni and Laurent, 1986) method was used to determine thermal diffusivity by sending a laminar flow in a very short time. The methods used for the thermal characterization had proven their efficiency using just one sample contrary to the old method which consists of two samples.

Table 2 Chemical composition of clay

Chemical element	Percentage of chemical element (%)
SiO ₂	59.6
Al ₂ O ₃	22.4
Fe ₂ O ₃	6.69
CaO	0.0777
MgO	0.97
K ₂ O	2.53
TiO ₂	0.832
P ₂ O ₅	0.458
P.a.f	5.34

**Fig. 7** Apparent density of the composites clay-cork according to the volume fraction of cork.

Results and Discussions

The apparent density was calculated according to the dimensions and masses of samples and the thermal properties were measured using the Hot plate and Flash methods. The results are described as below.

Composites Clay-Cork

Density of composites clay cork

Fig. 7 shows the apparent density of clay cork versus the volume fraction of cork. The curve indicates that for the highest volume fraction of cork, the density is 1114 kg m^{-3} . However, the density of clay alone is 2029 kg m^{-3} which proves a gain in term of lightness for the composites clay-cork of 45%. The decrease of density is explained by the porosity created by cork inside the matrix clay. As a conclusion of these results, the insulator material cork introduces the air inside the matrix clay and become lighter in weight.

Thermal conductivity of composites clay cork

Fig. 8 below shows the plot of thermal conductivity versus volume fraction of cork. As the volume fraction of cork in the composite increases, the composite thermal conductivity decreases. At the highest volume fraction of cork, thermal conductivity of the composite is $0.24 \text{ W m}^{-1} \text{ K}^{-1}$, while, the thermal conductivity of clay is $0.51 \text{ W m}^{-1} \text{ K}^{-1}$. This proves an improvement of the insulating properties by 50%.

Thermal diffusivity of composites clay cork

Fig. 9 shows the relationship between thermal diffusivity and volume fraction of cork. Analysis of this curve indicates that the thermal diffusivity decreases from $5.10^{-7} \text{ m}^2 \text{ s}^{-1}$ to $3.10^{-7} \text{ m}^2 \text{ s}^{-1}$ by adding cork. This is a reduction of 39% thermal diffusivity which improves the thermal inertia of the clay. A linear fit was made to calculate thermal diffusivity according to the volume fraction of cork.

Fig. 8 Thermal conductivity of the composites clay-cork according to the volume fraction of cork.

Fig. 9 Thermal diffusivity of the composites clay-cork according to the volume fraction of cork.

Fig. 10 Thermal effusivity of the composites clay-cork according to the volume fraction of cork.

Thermal effusivity of composite clay cork

Fig. 10 shows thermal effusivity as a function of volume fraction of cork. Analysis of the curve demonstrates that thermal effusivity of clay is reduced by 40% when the volume fraction of cork is the highest. As a conclusion, granular cork minimizes heating of the superficial area of clay combined by cork.

Comparison and discussion of results using different methods

Fig. 11 shows the plots of thermal conductivity versus cork volume fraction of composite for different theoretical models. According to the results of thermal conductivity of the composite clay-cork as illustrated in the **Fig. 11**, the equivalent thermal

Fig. 11 Graphical representation of the different theoretical models of the equivalent thermal conductivity of the composite clay-cork.

Fig. 12 Apparent density according to the size of cork.

conductivity is between the lower limit (series model) and the upper limit. However, the experimental data is more representative by the geometric model which estimates that the particular cork possesses a preferred orientation according to their natural segregation. Also, they have a special geometrical form between a spherical and cylindrical with a spherical value $\xi = 0.5$. The Hamilton model is more close to the experimental results. The Beck model is in the center of the equivalent thermal conductivity. In reality the real distribution of this composite is between the series and the parallel model.

Composites Cement Mortar Cork

Density of composites cement mortar cork

Fig. 12 shows apparent density of materials based on mortar cement and cork. The results demonstrate that cork has a significant effect in reducing the density of mortar. The density decreased from 1854 to 1180 kg m^{-3} when cork was added to mortar cement. The different volume fraction of cork has insignificant effect on the density of the composite cement mortar. The reduction of density is due to the creation of porosity inside the matrix mortar cement.

Thermal effusivity

Fig. 13 illustrates a clear impact of cork in decreasing the thermal effusivity by 60% compared to mortar cement alone. Different sizes of cork are showing approximatively the same impact.

Thermal conductivity

Fig. 14 shows the thermal conductivity mortar cement with various cork sizes in the composite. The composites cement mortar-cork possesses high insulating properties in comparison with cement mortar alone. Thermal conductivity decreases from 0.703 to 0.207 $\text{W m}^{-1} \text{K}^{-1}$ as the cork sizes changes and a reduction of 70% was obtained. Another observation made is that the variation of cork sizes does not influence significantly on the value of the thermal conductivity. The decrease of this property for the composites cement mortar-cork is due to the creation of air inside the matrix cement. The thermal conductivity of the air in

Fig. 13 Thermal effusivity according to the size of cork.

Fig. 14 Thermal conductivity according to the size of cork.

Fig. 15 Thermal diffusivity of the composites cement mortar-cork according to the size of cork.

ambient temperature is $0.025 \text{ W m}^{-1} \text{ K}^{-1}$. [Bachar et al. \(2015\)](#) also got similar findings in their investigation to determine the effect of porosity of cork on mortar cement.

Thermal diffusivity

Fig. 15 shows thermal diffusivity of the composite with various cork sizes in it. When the corks size is 8–12.5 mm, thermal diffusivity decreases to $2.23 \times 10^{-7} \text{ m}^2 \text{ s}^{-1}$ from that of cement mortar only. This gives a reduction of 40% compared to thermal diffusivity of mortar cement $3.74 \times 10^{-7} \text{ m}^2 \text{ s}^{-1}$. This proves that the highest size of cork retards best the acceleration of heat flow inside the matrix mortar cement.

Comparison of results with literature

The results obtained were compared with that of [Borges et al. \(2018\)](#) to compare the effect of cork on cement mortar composite. [Borges et al. \(2018\)](#) prepared two varieties of twenty samples of composites made of cement-expanded cork and cement-expanded clay and studied the effect of various cork sizes on the thermal and mechanical properties of the composites. Their results have shown that mixture of cement and expanded cork gave the lowest bulk density (52 kg m^{-3}) and the mixture of cement and expanded clay produced the highest bulk density (431 kg m^{-3}). Also, they explained that mortars with expanded cork granules presented the lowest thermal properties with a reduction of 93%–94% while the highest values were achieved by mortars with expanded clay and this result can be explained by the best thermal behavior of cork due to its uniform closed cells structure that hinders the heat transfer by convection.

Composites White Cement Cork

Density of composites white cement cork

Fig. 16 shows apparent density of composites white cement cork for various cork sizes. The results demonstrate that cork has a significant effect in reducing the density of white cement. The density decreased from 1571 to 821.5 kg m^{-3} when cork size was 8–12.5 mm. The different volume fraction of cork has insignificant effect on the density of the composite white cement. The reduction of density is due to the creation of porosity inside the matrix of white cement.

Thermal conductivity of composites white cement cork

Fig. 17 shows the thermal conductivity white cement cork with various cork sizes in the composite. The composites of white cement cork possess high insulating properties in comparison to white cement alone. Thermal conductivity decreases from 0.86 to $0.207 \text{ W m}^{-1} \text{ K}^{-1}$ as the cork size is 8–12.5 mm changes and a reduction of 76% was obtained. The corks sizes of 5–6.3 mm and 6.3–8 mm in the composite yielded the same thermal conductivities.

Fig. 16 Apparent density of the composites white cement-cork according to the size of cork.

Fig. 17 Thermal conductivity of the composites white cement-cork according to the size of cork.

Fig. 18 Thermal effusivity of the composites white cement-cork according to the size of cork.

Fig. 19 Thermal diffusivity of the composites white cement-cork according to the size of cork.

Thermal effusivity of the composites white cement cork

Fig. 18 shows thermal effusivity of composites based on white cement and various cork sizes. There is a distinct effect of cork in decreasing the thermal effusivity by 57% compared to white cement alone. Different sizes of cork have approximatively the same effect on thermal conductivity.

Thermal diffusivity of composites white cement cork

Fig. 19 shows thermal diffusivity of white cement composite with various cork sizes in it. Thermal diffusivity decreases from 3.24×10^{-7} to $2.08 \times 10^{-7} \text{ m}^2 \text{ s}^{-1}$ from white cement to white cement composite when the cork size is 8–12.5 mm. This gives a reduction of 36% compared to thermal diffusivity of white cement of $3.24 \times 10^{-7} \text{ m}^2 \text{ s}^{-1}$. This proves that the highest size of cork retards best the acceleration of heat flow inside the matrix mortar cement. The cork sizes do not have an influence on thermal diffusivity of the composite white cement cork.

Comparison of results with literature

A comparison of this result was made with the work of [Mounir et al. \(2015\)](#). They studied the effect of composites white cement-cork, mortar cement cork and plaster-cork on the thermal inertia of building by analyzing the thickness of heat diffusion according to a time interval of 3 h, 6 h, and 12 h. Their results showed that the thickness decreased from 5.82 to 5.32 cm at 3 h, 8.24–7.52 cm at 6 h, and 11.65–10.18 cm at 12 h. This proves the improvement of thermal inertia characteristics using cork in the composite.

Conclusion

This work is divided in two main sections: physical-chemical characteristics of cork and thermal performance of material clay, mortar-cement and white cement joints to cork. A lot of parameters such as apparent density using the weight and the dimensions of samples, thermal conductivity, thermal effusivity using the asymmetrical hot plate method and thermal diffusivity using flash method were studied. With regard to the material clay, the study was focused on the variation of the volume fraction of cork and

its effect on the thermal performance and density. Results show that at the highest volume fraction (0.491), a reduction of weight by 45%, a gain on insulating properties by 51%, and an improvement of thermal inertia by a ratio of 40% was obtained. Also, equivalent thermal conductivity was studied to see the most representative model. It was observed that the geometric model was close to the experimental results which, proves that granular cork is well distributed inside the matrix clay. For the mortar cement and white cement composites, the effect of the cork sizes cork was studied. Results showed that cork possesses some important characteristics in reducing lightness. Thermal properties and thermal inertia of these composites materials, the composite mortar cement-cork showed a reduction of lightness of 36%, a reduction of 76% on thermal characteristics and an improvement of 40% of thermal inertia parameter. Although, for the composite white cement-cork, lightness was improved by 47%, insulating properties was improved by 76% and the thermal inertia parameters were reduced by 40% compared to white cement alone. The variation of the cork sizes does not have any influence on the lightness and thermal performance of the mortar cement and white cement cork composites.

Polyhydroxyalkanoate and Polylactic Acid Composite

Md SI Mozumder, Shahjalal University of Science and Technology, Sylhet, Bangladesh

© 2020 Elsevier Inc. All rights reserved.

Introduction

Plastics have become an indispensable part of our daily life. Since the 1950s, the production of plastics has shown a steady increase with about 9% per year. Global production reached 335 million tons in 2016. The production of plastics is so far mainly based on fossil fuels and takes place through energy intensive petrochemical processes. The environmental impact of these conventional fossil-based plastics is not associated only to their production process, but also to their non-biodegradability, making them persistent to the environment. They are therefore becoming a serious pollution issue. The world's growing environmental awareness and limited fossil fuels reserves have directed research and industrial attention towards the production of bioplastics as alternatives for petrochemical based synthetics plastics. Bioplastics encompass the materials which are either biobased or biodegradable or both. They can be produced fully or partially from biomass and can be tailored to be fully or partially biodegradable (Table 1).

The market of biopolymers is growing every year and demands can be expected from the applications of biopolymers-based product which offer clear benefits for customers and environment. A report published by BCC Research (a market research company) has estimated that in 2014 the global bioplastic demand was more than 1400 kt (metric kilo tonnes), whereas it was predicted an increasing to about 6000 kt in 2019, which represents a CAGR (compound annual growth rate) of 32.7% for the five-year period; from 2014 to 2019 (Chen, 2014). Furthermore, from the correlation of the demand of bioplastics, it is expected that the global production capacities will be increased to more than 7.8 million tonnes in year 2019. At that time, within the bio-based polymer the biodegradable part will be only 16%.

The rapid emergence of bioplastics is one of the major stories of the last decade (Chen, 2014). Unfortunately, for certain requirements such as in packaging or engineering sectors, the biopolymers cannot be fully competitive with polymers from the category of commodity or engineering thermoplastics (e.g., PS, PE, PP, PET, etc). In order to maximize the impact of biopolymers, there is a growing trend to combine bio-polymers, a key-approach allowing to extend their consumption and market as durable products used in cars, electronics, and elsewhere. The focus has shifted to the total "carbon footprint", and the bio-based polymers not only can replace existing polymers in various sectors but can also provide new combinations of properties and extended applications.

Polyhydroxybutyrate (PHB) being considered as bio-plastics, has the potential to substitute the conventional plastics as it has the similar material properties of polypropylene (PP). But till PHB has not been used on a large scale to replace conventional polymers because of its drawbacks in mechanical properties. It is hard to process PHB due to its high melting temperature of approximately 170°C, which is very near to its degradation temperature (Hazer and Steinbuchel, 2007). Therefore, a solution to these drawbacks could be the copolymerization of hydroxybutyrate with other monomers or making composite with other polymer that confer less stiffness and tougher properties (which bestow greater flexibility and lessen breakage) and to reduce the melting point.

Polylactic acid (PLA) has good mechanical properties particularly, high tensile strength, young's modulus and good flexural strength, which are even higher than those of polystyrene (PS), PP, polyethylene (PE), or other conventional polymers (Hamad et al., 2015). The tensile strength and elastic modulus of PLA are comparable to those of polyethylene terephthalate (PET), but unfortunately PLA is very brittle, with less than 10% elongation at break and low toughness, which limits its use in applications that need plastic deformation under high stress (Rasal et al., 2010). For packaging applications, it is stated that PLA films have mechanical properties comparable to those of PET, whereas the lower glass transition temperature is considered a disadvantage,

Table 1 Classification of plastics based on source and biodegradability

	Fully petroleum based	Partially biobased	Fully biobased
Fully biodegradable	● PBS ● PCL	● Starch blends ● PLA blends	● PLA ● PHA ● PLA/PHA composites
Non biodegradable	● PE ● PP ● PET ● PVC	● PA ● PET from biobased ethylene ● PVC from biobased ethylene ● SBR from biobased succinic acid	● Biobased PE ● Biobased PB

Source: PA = Polyamide, PB = Polybutadiene, PBS = Polybutyrate succinate, PCL = Polycaprolactone, PE = Polyethylene, PET = Polyethylene terephthalate, PHA = Polyhydroxyalkanoate, PLA = Polylactic acid, PP = Polypropylene, PVC = Polyvinyl chloride, SBR = Styrene butadiene rubber.

especially in applications (e.g., hot packaging) requiring resistance at high temperature. Regarding the characteristics of films, the gas permeability coefficients to CO₂, O₂, N₂ and H₂O(g) have been reported as being higher than for PET, therefore these properties need further improvement.

Polyhydroxyalkanoates (PHAs)

Structure, Properties and Sources

Among the alternatives of different bioplastics, an interesting bioplastic are the fully biobased and biodegradable polyhydroxyalkanoates (PHAs). It is synthesized by a number of microorganisms as intracellular storage material. PHAs constitute an attractive alternative to petrochemically synthesized plastics due to their comparable physical and chemical properties, and because of their biodegradability and biocompatibility as additional advantages.

PHAs are polyesters of hydroxyalkanoic acids, composed of hydroxy fatty acids with the most common structure shown in Fig. 1. The side group (R in Fig. 1) varies from methyl (C₁) to tridecyl (C₁₃). PHAs are termed polyhydroxybutyrate (PHB) if R is a methyl (-CH₃) group, polyhydroxyvalerate (PHV) if R is an ethyl (-CH₂CH₃) group, and polyhydroxyhexanoate (PHHx) if R represents a propyl (-CH₂CH₂CH₃) group.

Polyhydroxybutyrate (PHB) is the most common and well-studied PHA which was first isolated and characterized by Lemoigne in 1925. Since then, a number of studies have been performed with various bacterial strains such as Gram-positive bacteria, Gram-negative bacteria, photosynthetic bacteria including cyanobacteria which one has identified the highest PHA production capacity. The microorganisms are stimulated to produce PHAs when the ratio of substrate to nutrients in the culture medium is high, but intracellular degradation of PHAs occurred in absence of carbon and energy sources. By the year 1973 it was well recognized that the storage material PHAs fulfilled a similar role for bacteria as starch and glycogen for higher organisms i.e., eukaryotic (Dawes and Senior, 1973).

At the beginning of the invention, it was thought that the produced PHA was a homopolymer, comprising hydroxybutyrate (3HB or 4HB) as the sole monomer. Later, it was discovered that PHA also contained other types of monomers besides the already present 3HB or 4HB such as hydroxyvalerate (HV), hydroxyhexanoate (HHx), hydroxyheptanoate (HHp), hydroxyoctanoate (HO) to produce co-polymers such as P(3HB-co-3HHx), P(3HB-co-4HB), P(3HB-co-3HV) etc. Besides, a large variety of monomers with straight, branched, saturated, unsaturated and also aromatic structures were also found as a constituent in copolymers of PHB. The presence of various monomers in the copolymer appeared to be dependent on the substrate used as carbon and energy source.

Production Process of Polyhydroxyalkanoates (PHAs)

Pure-culture PHAs production processes

Pure culture PHAs production process is conducted either non-growth associated or growth associated. Due to higher productivity, most of the cases it followed non-growth associated process which consists two phases; first one is biomass growth under favourable condition especially at optimal level of carbon, nitrogen and oxygen concentration and second phase is PHAs accumulation under nutrient limiting condition (Fig. 2(a)). The process is either in batch or fed-batch. The growth associated PHAs production is a single stage process in which growth and production is conducted at same time (Fig. 2(b)).

PHAs production through microbial fermentation takes place under heterotrophic and/or autotrophic conditions. While most works were carried out using organic substrates as carbon source, i.e., heterotrophic PHAs production. There are also some attempts to produce PHAs from carbon dioxide (CO₂), i.e., autotrophic or heterotrophic-autotrophic PHAs production, using hydrogen (H₂) as an energy.

Heterotrophic process

Heterotrophic PHAs production is a bioprocess that uses an organic substrate as carbon and energy source. The provided substrate is able to support bacterial growth, maintenance functions and reserve polymer synthesis.

Pure culture heterotrophic PHAs production was mainly focused in most of the research and industrial production. Under optimal process conditions, the microorganisms have the ability to accumulate PHAs until 80% of the cell dry mass (CDM) (Posada *et al.*, 2011).

Fig. 1 General structure of a polyhydroxyalkanoate (PHA).

Fig. 2 Schematic presentation of PHAs production in a pure culture system (a) non-growth associated and (b) growth associated.

Heterotrophic biomass growth on an organic substrate proceeds mostly according to the following equation:

In Eq. 1, $C_wH_xO_y$ denotes the organic substrate, and $CH_{1.74}O_{0.46}N_{0.19}$ is the chemical composition of *Cupriavidus necator* biomass (without PHAs), a model organism for PHAs production (Ishizaki and Tanaka, 1990). Y_X is the yield of biomass over organic substrate. During cultivation, oxygen (O_2) and NH_4^+ as a nitrogen source are mandatory for bacterial growth as an electron acceptor and as a nutrient source respectively and CO_2 is produced as a side-product. PHAs production is suppressed due to excess of NH_4^+ -N.

Heterotrophic PHB (one of the most common PHAs) production from an organic carbon source is represented according to the Eq. 2.

Here $C_4H_6O_2$ is the chemical composition of PHB monomer. Y_P is the yield of PHB over organic substrate.

Most lab-scale studies and established industrial processes for PHAs production work with pure sugars such as glucose, fructose, sucrose etc. as carbon source, ensuring high productivity and proper metabolic functioning of the strain. Nevertheless, these substances are expensive and several efforts have been developed to identify low cost carbon sources, namely industrial and agricultural waste substrate such as waste glycerol, molasses, dairy whey, corn syrup, starch residues etc. There are still some concerns about the final PHAs content as well as a high productivity.

Two prevalent cultivation methods are employed for pure culture PHB production, depending on the microorganism used; growth associated and non-growth associated mode.

Growth associated PHAs production

Growth associated PHAs production is a one step process, in which PHAs production is conducted in parallel with bacterial growth. In this case there is low nutrient inhibition effect on the PHAs production. Organisms like *Bacillus mycoides*, *Azohydromonas lata* etc., are able to produce PHAs in growth associated mode with high productivity in a nutrient rich medium.

Non-growth associated PHB production

The non-growth associated manner consists of two phases. First, biomass is grown under favourable conditions especially at optimal level of carbon, nitrogen and oxygen (O_2) concentration. The second phase is PHB accumulation under nutrient limiting conditions namely nitrogen or oxygen limitation. Due to the higher productivity, the pure culture non-growth associated process to produce PHAs attract major attention.

Table 2 Comparison of PHB production and productivity using *Cupriavidus necator* (formerly known as *Ralstonia eutropha* and *Alcaligenes eutrophus*) as an organism in a fed-batch fermentation process in order of increased PHB concentration

Substrate	Strain and mutant	Feeding of organic substrate	CDM concentration (g/L)	PHB production (g/L)	PHB content (%)	PHB productivity (g/L/h)	Reference

Various bacteria have the ability to synthesize PHAs such as *Cupriavidus necator*, *Alcaligenes latus*, *Azotobacter vinelandii*, certain *Pseudomonas* as well as genetically modified *Escherichia coli* strains etc. Among them *C. necator* (also named as *A. eutropha*, *C. eutropha* or *R. eutropha*) is the most extensively studied micro-organism due to its high productivity (Ashby *et al.*, 2002). It can produce significant amounts of PHAs from different carbon substrate such as glucose, fructose, glycerol, oil and even waste substrate (Table 2).

Autotrophic process

The autotrophic process is the process at which CO₂ is used as carbon source. In this process a gas mixture of CO₂, H₂ and O₂ is used for cell growth and PHAs production. Hydrogen oxidizing bacteria such as *C. necator* have the ability to grow and produce PHAs through autotrophic metabolism, using CO₂ as carbon source and H₂ as energy source (Table 2). CO₂ is a greenhouse gas of which the concentration in the atmosphere is related with the global warming phenomenon. In attempts to counteract climate change, emitted CO₂ can be a valuable source of carbon which can be utilized in the production of commercially valuable products such as PHAs. Autotrophic biomass growth (Eq. (3)) and PHB production (Eq. (4)) are described by the following equations.

Until now autotrophic PHAs production has only been conducted in pure culture non-growth associated manner using *C. necator* as organism. The gas composition which attains sufficient cell growth has a ratio of $H_2:O_2:CO_2=7:2:1$ (Mozumder *et al.*, 2015). Such a gas composition lies completely within the gas-explosion range and is therefore too dangerous to work with. Considering safety issues, the O_2 concentration in the gas phase should be kept below the lower level of explosion (LEL) for O_2 , between 6 and 6.9 vol% (Takeshita and Ishizaki, 1996). However, under those low O_2 concentrations, limited growth as well as low PHAs production were achieved.

Heterotrophic-autotrophic process

The heterotrophic-autotrophic process consists of a heterotrophic phase for exponential growth using an organic substrate promoting a high cell density culture followed by an autotrophic phase for PHAs production using a gas mixture of CO_2 , O_2 and H_2 at an O_2 concentration under the LEL. The advantage of this cultivation system is that a high cell concentration can be obtained as O_2 can be supplied under non-limiting conditions during the heterotrophic cell mass growth phase, while in the autotrophic phase PHAs biosynthesis will be triggered when the O_2 concentration is below its critical value of LEL.

Two organism cultures of PHAs production

In pure culture it was proven that *C. necator* was an efficient microorganism for PHAs production, but it cannot easily metabolize sucrose. This limitation can effectively overcome using the two-organism culture method by a two-reactor system; in first phase sucrose was converted to lactate by lactate producing organism (such as *Lactococcus lactis*) and then followed PHAs production by *A. eutropha* (Tanaka and Ishizaki, 1994). The overall process flow is shown in Fig. 3. The process has mainly three phases; (1) conversion of sucrose or higher hydrocarbon to easily metabolite form of hydrocarbon; for example, production of Lactate through lactate producing bacteria, (2) growth of PHAs producing organism under sufficient Lactate and nutrient conditions and (3) PHAs production under nutrient stress condition. Although in literature the process was called a mixed culture, two pure microorganisms are used and followed nutrient stress condition to stimulate the PHAs production, same as the mechanism of pure culture. There is also possible to use single bioreactor instead of two for this two-organism system; initially inoculated pure *L. delbrueckii* to ensure the sufficient conversion of lactate and then pure *C. necator* was injected to same bioreactor for the synthesis of PHAs. However, the competition between both organisms is not still clear.

Mixed culture PHAs production

Mixed culture operation had been evaluated aiming to conversion of waste material to valuable product like PHAs and to reduce the capital and operational expenses. The process is known as 'feast and famine'; in which substrate availability alternated periodically, explained in Fig. 4. In feast famine process, the substrate uptake rate reaches its maximum value after the addition of substrate, as well as the cell growth rate slowly reached to the maximal level. In the transient period the excess of substrate was taken up and stored into the cell as PHAs. After depletion of the external substrate, the stored PHAs is used for cell growth. The most accepted explanation, PHAs synthesis occurred when the growth was limited by internal factors such as insufficient amount of RNA or enzymes required for growth. Feast famine process also implemented in aerobic activated sludge system where sludge is submitted periodically as an external carbon source for PHAs storage. Indeed, the intracellular PHAs content was reached around 70% of the cell dry weight, suggesting that this process could be competitive with pure culture PHAs production when fully developed (Dias *et al.*, 2006).

Fig. 3 Stoichiometric representation of PHAs production by a two-organism mixed culture system.

Fig. 4 Schematic representation of PHAs production through mixed culture feast famine process.

Application of PHAs

The wide range of properties of PHAs and its copolymers make it an attractive biopolymer for various applications involving packaging, medical and coating materials. However the main obstacle behind the limited application of PHAs is to produce a specific copolymer with desired properties.

Industrial applications

PHAs is used to make small disposable articles such as shampoo bottles and packaging materials including food packages. It is also used for bags, paper, disposable utensils, cups etc. Foils, films and diaphragms can also possible be made with PHAs (Lauzier *et al.*, 1993). PHAs latex can be used as water-resistance surface of cover paper or cardboard. Hard articles such as combs, pens etc., are made of P(3HB) because of its high crystallinity (Chen and Wu, 2005). The copolymer P(3HB-co-3HHx) is used to make flushable, nonwovens, binders, flexible packing, thermoformed articles, synthetic paper and medical devices. P(HB-HV) has gas barrier properties and is useful for food packaging, plastic beverage bottles, coated paper milk cartons etc. PHB blend with polyhydroxyoctanoate (PHO) is also known as an elastomer for the production of food additives (Clarival and Halleux, 2005).

Medical applications

PHB and its copolymers are extensively used as pharmaceutical products in surgery, transplantology, tissue engineering, pharmacology etc. In tissue engineering, the cells are grown *in vitro* on PHAs to construct "tissue" for implantation purposes (Shinoka *et al.*, 1998). PHB and P(HB-co-HHx) are the most extensively studied biopolymers for tissue engineering and controlled internal drug delivery system. PHB has also been found to be a suitable scaffold for preparing autologous cardiovascular tissue (Shangguan *et al.*, 2006).

PHB is frequently used as bone plates, osteosynthetic materials and surgical sutures. Hydroxyapatite ($\text{Ca}_5(\text{PO}_4)_3\text{OH}$) incorporated into PHB can be used in hard tissue regeneration (Doyle *et al.*, 1991). The combination of hydroxyapatite with PHB and P(HB-HV) leads to similar mechanical strength as that of human bones which is beneficial for bone tissue engineering (Galego *et al.*, 2000). The graft copolymer of methyl methacrylate and PHB blocks can be used as bone cement in orthopaedic applications. Moreover, the biocompatible property of PHB makes it well-suited for skincare products (Chen and Wu, 2005).

Polylactic Acid (PLA)

Production of Polylactic Acid (PLA)

The synthesis of PLA polymers can be performed by direct polycondensation of lactic acid as well as by ring-opening polymerization of lactides, a cyclic dimer of lactic acid. Before the production reaction to PLA, either lactic acid or lactides are needed to produce.

Synthesis of lactic acids

Stereoisomers of lactic acid

Lactic acid chemically named as 2-hydroxypropanoic acid, is the simplest 2-hydroxycarboxylic acid with a chiral carbon atom. There are two optically active stereoisomers of lactic acid namely L and D enantiomers; L- and D-lactic acid, respectively (Fig. 5). These L- and D-lactic acids are generally synthesized through fermentation using organic carbon source and suitable microorganisms. Racemic DL-lactic acid is also existing which consist equimolar mixture of D- and L-lactic acids, shows different characteristics from original single lactic acids and synthesized by chemical method rather than fermentation.

Fig. 5 Structure of L-, D-lactic acids.

Lactic acid production through fermentation

Lactic acid is mainly produced through fermentation using lactic acid bacteria. Worldwide it is counted that around 90% lactic acid is produced through fermentation. The fermentation process has attracted interest because of its numerous advantages compared with chemical synthesis, such as production of pure isomers, the use of renewable resources as substrates etc. Several microorganisms and raw materials can be used in the production of lactic acid. Using pure substrate such as sucrose from sugarcane and sugar beet etc. produce highly pure Lactic acid, results in a reduction in the cost of purification. Unfortunately, the high cost of pure substrate such as sugar makes it unfeasible for industrial application. The waste products from food industries, agricultural industries, sugarcane mills, and biomasses can be used, which is advantageous from an environmental and economic standpoint.

Lactic acid bacteria are generally divided into several classes in terms of cell morphology, i.e., *Lactobacillus*, *Streptococcus*, *Pediococcus*, *Aerococcus*, *Leuconostoc* and *Coryne* species. Most of them produce L-lactic acid and few of them are able to produce D- or DL-lactic acids. The species belonging to the same *Lactobacillus* genus can produce either L- or D-lactic acid. *Lactobacillus helveticus* and *Sporolactobacillus* produce DL- and D-lactic acids, respectively, however, depending on operating conditions, sometimes small amounts of both L- and D-lactic acid also can be produced.

Chemical synthesis of lactic acid

Racemic DL-lactic acid can be synthesized by fermentation using appropriate bacteria, but it is more easily to synthesize it by following the chemical process shown in Eqs. (5) and (6). Here, the DL-lactic acid is produced by hydrolysis of lactonitrile that is generally formed by the addition reaction of acetaldehyde and hydrogen cyanide. Industrially, the lactonitrile is obtained as a by-product of acrylonitrile production. The reactions involved for DL-lactic acid production are described in Eqs. (5) and (6).

At first hydrogen cyanide (HCN) is added to liquid acetaldehyde (CH_3CHO) in presence of a base catalyst under high pressure to produce lactonitrile (Eq. (5)). The lactonitrile is then recovered, purified by distillation, and hydrolyzed using sulphuric acid (H_2SO_4) to produce lactic acid ($\text{CH}_3\text{CHOHCOOH}$) (Eq. (6)).

Although there are many possible routes for the production of lactic acid by chemical synthesis, none of these routes are technically and economically feasible, except for the routes that use lactonitrile as the raw material.

Separation and purification of lactic acids

The fermenting liquor obtained from fermentation process contains lactic acid with various impurities such as un-reacted raw materials, cells and culture media-derived saccharides, amino acids, carboxylic acids, proteins and inorganic salts. Therefore, the isolation and purification of Lactic acids are needed for obtaining a highly pure product as well as polylactic acid (PLA) synthesis. Effective separation and purification of lactic acid from fermentation broth is extremely important for economic viability. Although the difference between the boiling point of lactic acid and water is relatively large, it is almost impossible to obtain pure crystalline lactic acid. This is due to a high affinity of lactic acid to water and formation of a dimer lactate at high concentration of lactic acid.

The separation and purification of Lactic acid involves a series of downstream process such as precipitation, conventional filtration, acidification, carbon adsorption, evaporation, crystallization, etc (Pal et al., 2009). The number of steps involved in downstream processing, strongly influences the quality and the price of the product.

Every purification technologies have several advances, but many drawbacks are still reported. In precipitation process, the reagents cost is very high and necessity of filtration and other separation processes, while high product purity is required. It generates large amounts of waste water which is a major drawback. Furthermore, to produce one ton of lactic acid, approximately one ton of calcium sulphate is needed (Pal et al., 2009), which poses serious problems in treatment of produced waste. In solvent extraction process, a high surface area is necessary for the efficient separation – make the process expensive. The in-situ application of solvent extraction process is not possible due to limited solvent recovery and toxicity to microorganisms (Gao et al., 2009). The membrane separation processes are promising technologies for the efficient separation, but its application in large scale is limited by its high cost of membranes and polarization and fouling problems.

In recent years, a number of studies have been completed to solve the problems by improvement of traditional separation process, such as applying reactive distillation (Kumar *et al.*, 2006; Lunelli *et al.*, 2010) and molecular distillation (Chen *et al.*, 2012; Komesu *et al.*, 2014). In this process lactic acid is first esterified with methanol (CH₃OH) to produce methyl lactate (CH₃CHOHCOOCH₃) (Eq. (7)). The produced methyl lactate is recovered, purified by distillation, and hydrolyzed in an acidic medium to produce lactic acid and methanol (Eq. (8)). Methanol is separated by distillation and recycled.

Furthermore, more studies on lactic acid recovery processes are required to develop a more efficient and economically attractive process for industrial applications.

Synthesis and purification of lactides

Lactides is the cyclic dimer of lactic acids. It is usually synthesized by depolymerization of corresponding lactic acid that is obtained by polycondensation of relevant lactic acid. At first water is removed by a continuous condensation of aqueous lactic acid to produce low molecular weight oligomers or prepolymers. The oligomers or prepolymers is then catalytically converted to lactides through an internal transesterification reaction. Because of the ring-chain equilibrium between lactide and oligomers or prepolymers, unzipping depolymerization generates lactide through the back-biting mechanism involving the -OH terminals as the active site. This reaction is well catalysed by metal compounds involving Sn, Zn, Al and Sb ions, etc. The crude lactide can be purified by melt crystallization or ordinary recrystallization from solution or distillation under vacuum.

There are three potential forms of lactides: D,D-lactide called D-lactide, L,L-lactide called L-lactide and L,D- or D,L-lactide known as meso-lactide (Fig. 6). Only D- and L-lactide are optically active stereoisomers. The meso-lactide is up to two times more susceptible to reactions than L-, D-, or racemic lactides, which can mean less catalyst usage, lower processing temperatures, or both for meso-lactide.

Polymerization of lactic acids and lactide monomers

There are two major routes to produce polylactic acid (PLA) at industrial scale:

- (1) Direct polycondensation of lactic acid (LA)
- (2) Ring-opening polymerization (ROP) via lactide

In direct polycondensation of lactic acids, at first water was removed by condensation and then used solvent under vacuum pressure and high temperature to produce PLA. There are several disadvantages of this process such as, only low to intermediate molecular weight PLA can be produced due to the difficulties of removing water and impurities, relatively large reactor required, the need for evaporation, recovery of the solvent, significant change of colour and racemization (Farrington *et al.*, 2005). Using chain-extension method with low or intermediate molecular weight PLA high molecular weight PLA is possible to produce, but the properties of PLA obtained in this way can be affected. Azeotropic distillation using a high boiling solvent to remove the water from lactic acids before polymerization is another alternative to produce high molecular weight PLA (Murariu and Dubois, 2016).

Industrial production of PLA mostly based on ring-opening polymerization (ROP), the main way to obtain high molecular weight PLA. It is carried out by commonly using a stannous octoate based catalyst. Currently, industries focusing on a multi-step procedure involving the ROP of lactide without using any solvents. It starts with the condensation reaction of aqueous lactic acids to produce low molecular weight PLA prepolymer followed the conversion into a mixture of lactide stereoisomers using tin (Sn) catalysis to enhance the rate and selectivity of intramolecular cyclization reactions. The impurities are removed in a distillation step, and the meso-lactide is separated. The "meso" fraction is then combined with the low D-lactide fraction and high L-lactide fraction to produce a large portfolio of PLA grades. The high molecular weight PLA is produced using an organo-tin catalyst. It is also help to eliminate the use of costly and environmentally unfriendly solvents (Farrington *et al.*, 2005). After polymerization, the residual lactide monomer is recycled within the process.

Recently another catalytic process has developed to make the process economically viable (Jacobsen and Fritz, 1999). In this new catalytic system, an equimolar amount of triphenylphosphine and stannous octoate is used for the polymerization of lactide by reactive extrusion. It has the advantages of low residence time and specific features, especially where is used the twin-screw extruder as "reactor" equipment.

Fig. 6 Stereoisomers of Lactides.

Properties of PLA

The polymerization of pure L- and D-lactides gives isotactic homopolymers of Poly(L-lactide) (PLLA) and Poly(D-lactide) (PDLA), respectively. Both of them are crystalline with a melting temperature 180°C and decrease with decreasing optical purity (OP) of the lactate (Liu *et al.*, 2013). Poly(DL-lactide) (PDLLA), prepared from meso-lactides, is an amorphous polymer, having an atactic sequence of D and L- units. Stereo-block copolymers of PLA diversities of PLA polymers provide a broad range of physicochemical properties for PLA materials when processed.

Generally, PLA is thermoplastic polyester which has a good mechanical, thermal and optical properties with elastic modulus 3000–4000 MPa and tensile strength in the range 50–70 MPa (Murariu *et al.*, 2010; Sodergard and Stolt, 2002; Urayama *et al.*, 2001). But they have very poor elongation at break (2%–10%) and restricts the application potential of pure PLA. PLA has the glass transition temperature (T_g) between 55 and 65°C and brittle at room temperature (Anderson and Hillmyer, 2006; Bao *et al.*, 2012; Liu *et al.*, 2013). The impact resistance of PLA is about 13–20 kJ/m² for low crystallinity and 18–35 kJ/m² for high crystalline grades – very poor or low impact resistance (Anderson *et al.*, 2008; Grijpma *et al.*, 2002). The chemical stability of PLA can be adversely affected at processing temperatures. The commercially available PLAs are typically stabilized against thermal degradation. The presence of water in PLA processing have a significant effect of PLA characteristics, a large amount of hydrolysis occurs when PLA with high moisture. The appearance of PLA is affected by the crystalline content; amorphous or low-crystalline PLA is a clear material with high gloss while highly crystalline PLA is an opaque white material.

Applications of PLA

PLA is a high-strength and high modulus polymer with acceptable barrier properties and easy processing with conventional machinery. However, PLA applications are still limited due to its higher cost with respect to conventional materials, but also for its brittleness and low thermal stability (Huneaul and Li, 2007).

From the beginning of the PLA production, it has been used in medical applications such as biodegradable scaffold, catheter, tissue regeneration and many other devices where biodegradability and biocompatibility are important. PLA shows attractive results in regulation of angiogenic factors or gene transfer in growing tissues (Sheridan *et al.*, 2000), biodegradation in regeneration tissue, control of drug delivery systems to target organs and tissues etc.

Using of PLA in packaging industry, particularly food packaging, plays a fundamental role to reduce the disposal waste mainly non-renewable and non-biodegradable packaging materials. Food with PLA packaging is safe with no health risks to consumers under glass transition temperature (T_g). PLA shows better behavior than classical materials like polystyrene, cellophane, PET or LDPE in terms of barrier properties against radiation, water vapor, atmospheric which increase its potential to use in food packaging (Oliveira *et al.*, 2004).

PLA, due to its low cost and its fibre properties, is now considering one of the most promising bio-polymers for textile applications. It is used in knitted fabrics, non-woven textiles, headrest covers, vehicle seats, tarpaulins non-woven wipes, car and household wipes, personal care towels, diapers, napkins etc. PLA is also used in the home/office furnishing sector such as carpets, tiles and rugs, draperies, curtains, pillows cushions, mattresses, sofas etc.

Fibrous reinforcements within PLA decrease the overall cost and improve mechanical properties, while powdered fillers are used. PLA formulations by using natural fibre reinforcements improve its thermal properties and it can be used to make the objects that can use at high temperature such as applications in the automotive industry; Toyota and Ford have used PLA/fibre composites for the interior parts of their cars i.e., canvas roof, carpet mats etc. (Serizawa *et al.*, 2006). Moreover, Samsung and Toshiba used PLA for remote control and phone chassis, Sanyo for CD/DVD discs and cases and Fujitsu used for the hard-shell case of notebooks.

Polyhydroxyalkanoates and Polylactic Acid Composites

Although polyhydroxyalkanoates are biodegradable polymers and synthesized from renewable resources, their potential applications are hampered due to brittleness and formation of very large spherulites. The polyhydroxybutyrate (PHB) and polylactic acid (PLA) composite is one of the most studied composites, which exhibits mechanical properties that are intermediate between the individual components. The PHA/PLA blends were studied mainly to explore their miscibility, crystallization, morphology, mechanical properties and degradation behavior. The composites of PHA and PLA not only improve the performance and offset the high price of PHAs but also offer more scope to expand their range of applications.

Production of Polyhydroxyalkanoates and Polylactic Acid Composites

The production of PHA and PLA composites is realized using the following techniques:

(1) Melt-compounding:

Melt compounding is a typical procedure in which dry mixing of all or some of the components with high speed mixers is conducted that followed by compounding in a wide range of melt-blending equipment such as internal mixers, single- or twin-screw extruders, Buss kneaders, etc. The processing conditions such as shear stress, temperatures, mixing time, etc. are

determined by the types of equipment, nature of dispersed phase(s), blend composition, desired end-use product properties, etc. The polyester-based matrix (i.e., PLA, PHA) is very sensitive to temperature, shearing and hydrolysis, so that all precautions should be applied to avoid its degradation. To avoid hydrolysis the limit of the water content in PLA for all compositions is around 50–250 ppm independent of processing conditions. Reinforcements or fillers containing crystallization water also make problem in the process.

In the preparation of a PHA and PLA composites using a co-rotating twin-screw extruder; the melt mixing is carried out above the glass transition temperature (T_g) as amorphous polymer. The reason for using a twin-screw extruder is to ensure that all the specimens undergo the same thermal–mechanical history. After processing the polymers is dried in a vacuum prior to use.

The melt-compounding method is highly preferred in the context of sustainable development. It has several advantages such as it avoids the use of organic solvents which are not eco-friendly and can alter the life cycle analysis of PLA. It is easy to up-scale to larger-scale and to industry, whereas the twin-screw extrusion is the preferred method for polymer modification or for the addition of masterbatches, impact modifiers, fibres, fillers, additives, or of selected polymers, which can increase the performances of PHAs/PLA composites.

(2) *Solvent-based methods (e.g., solvent-casting):*

This process mostly used at small laboratory scale. Due to low quantities of active pharmaceutical ingredients, this technique is attracting the interest for the biomedical sector. The composite produced through this approach lead some differences in proprieties compare to those obtained using melt compounding. The film form of PHA/PLA blends is generally produced by solvent casting using a common solvent mainly chloroform, at room temperature. The solvent-casted film is inserted between two Teflon sheets and compression-molded by heating at 200°C for 1 min under a pressure of 75 kg/cm². After melting, samples are kept at a given crystallization temperature and isothermally crystallized for 3 days. Thermo-compression together with solvent-casting methods, showed better thermal stability and higher tensile strength (increased to 44 MPa from 17 MPa) than those obtained by solvent-casting. However, solvent-cast films were very ductile (elongation at break of 203%) compared to the films by compression-moulding (elongation of only 3%). The condition of thermo-compression such as heating temperature, pressure, compression time are differ based on application of the end product (Murariu and Dubois, 2016).

(3) *Other methods:*

Other possible methods for the production of PLA based composites are (i) polymerization of lactide on the surface of dispersed phases of PHA for better compatibility or higher performances, (ii) the physical blending of PLA (as fibres) with PHA fibres, (iii) co-extrusion (fibres, films, sheets), (iv) hot pressing using the film stacking method etc.

Characterisation of PHAs/PLA Composites

The PHAs/PLA composition and types of PHAs within the composite have a significant effect on the toughness, miscibility, crystallization, mechanical properties and hydrolytic degradation of PHA/PLA composites.

Physical properties

The composites prepared through the solvent-casting method is immiscible in amorphous state but blends prepared through the melt-compounding method showed greater miscibility due to the trans-esterification of PHAs and PLA at high temperatures in the formation of PHAs/PLA block (Zhang *et al.*, 1996). The composition of P(3HB)/PLA: 50/50 wt% blend reveals a separate phase while the P(3HB)/PLA: 30/70 wt% blend is a compatible one-phase system (Vogel *et al.*, 2008). The miscibility of the P(3HB)/PLA composite is strongly influenced by the molecular weight of PLA component; the PLA of molecular weight values below 18,000 exhibited greater miscibility (Koyama and Doi, 1997). P(3HB) is highly crystalline polymer, addition of PLA decreases its crystallinity and the P(3HB)/PLA composites with 80% PLA do not show any crystallinity at all (Zhang *et al.*, 1996). There is a contradictory finding as in most cases, the crystal growth rate of crystallisable component is depressed by mixing amorphous components; the addition of the completely amorphous P(3HB) component has accelerated the growth rate of PLA spherulites. However, PLA is a transparent polymer and increasing HV in the composites, decrease the transparency. P(3HB-co-3HV) copolymer has a dense structure that does not allow light to pass through it and decrease the transparency in the P(3HB-co-3HV)/PLA composites (Nanda *et al.*, 2011). The P(3HB-co-4HB) copolymer is found evenly distributed in the PLA matrix. With an increase in the P(3HB-co-4HB) copolymer content, the average particle size, indicated by the P(3HB-co-4HB) copolymer pores, is also increased; make completely an immiscible system.

Mechanical properties

The P(3HB)/PLA composites show a reduction in modulus and stress at break and an enhancement of the elongation at break. P(3HB)/PLA blend films were more hydrophilic than P(3HB) films and PLA component; shows faster hydrolytic degradation. The elongation at break of P(3HB)/PLA composites are intermediate between pure P(3HB) and pure PLA. PLA dominated composites shows better mechanical deformation properties (Vogel *et al.*, 2008). The addition of PLA to P(3HB-co-3HV) copolymer gradually increase the tensile strength and modulus due to low tensile strength of P(3HB-co-3HV) and higher tensile strength and modulus of PLA. The strain at break increases as the P(3HB-co-3HV) copolymer is incorporated into the PLA. The impact strength of neat

PLA is 30 J/m and for neat P(3HB-co-3HV), it is 49 J/m (Zhao *et al.*, 2013). Although the elongation at break for the P(3HB-co-3HV)/PLA composites are higher than the individual polymers, the impact strength is nearly equal to that of the PLA and the Young's modulus decreases as the amount of PLA increase (Nanda *et al.*, 2011; Zembouai *et al.*, 2013).

Addition of P(3HB-co-4HB) copolymer in PLA composites increase elongation at break, decrease of modulus and tensile strength. 20% P(3HB-co-4HB) content increase the elongation at break to a maximum value of 317% (Han *et al.*, 2012).

Thermal properties

The PLA was more thermally stable than the P(3HB-co-3HV) copolymer. The thermal degradation of P(3HB-co-3HV) copolymer occurred through a random chain scission at ester groups whereas the thermal degradation of PLA occurred through the cleavage of a bond on the backbone to form a cyclic oligomer (McNeill and Leiper, 1985). Therefore, the thermal stability of the P(3HB-co-3HV)/PLA composites can be improved by increasing the amount of PLA however, the decomposition temperature for all the composites are between the PLA and P(3HB-co-3HV) copolymer.

Some report says that the degradation of each polymer occurred separately in PHAs/PLA composites. For the P(3HB-co-3HV)/PLA composites, two weight loss peaks were observed, one at 290°C and the other at 375°C represent individual degradation of P(3HB-co-3HV) and PLA. The melting temperature do not correlate with the miscibility of the PHAs/PLA composites. The melting temperature (T_m) of P(3HB-co-3HV) copolymer is 152°C and for PLA, it is 170°C and the T_m for the composites was found to be in between these two polymers. Miscibility of any polymer can be determined by evaluating the glass transition temperature (T_g). A single T_g indicates the miscibility of the polymer. One single T_g for both PLA and P(3HB-co-3HV) copolymer was poorly observed. However, increasing P(3HB-co-3HV) copolymer in PLA reduce the T_g from 60 to 45°C (Nanda *et al.*, 2011). The T_g for P(3HB-co-4HB) copolymer is higher than that of PLA; P(3HB-co-4HB) composite with PLA reduce the T_g , with an unchanging T_g for the PLA.

The degree of crystallinity of any polymer composites depends on the orientation, the flexibility of the polymer chain and nucleation. Crystallization temperature (T_c) of PLA from decrease from 119 to 83°C with an increase of P(3HB-co-3HV) copolymer content due to the presence of PLA prevent the crystal growth of P(3HB-co-3HV) copolymer in the composites (Nanda *et al.*, 2011). The P(3HB-co-4HB) copolymer component in the composites shows lower T_g values as compared to the neat P(3HB-co-4HB) copolymer; with increasing P(3HB-co-4HB) content in P(3HB-co-4HB)/PLA composite decreases the T_g . This is due to the immiscibility, resulting in the existence of a phase interface between PLA and P(3HB-co-4HB) copolymer (Shibata *et al.*, 2006).

The chain end's enriched surroundings therefore enhanced the chain's mobility near the interface. P(3HB-co-4HB) enhance chain mobility near the interface and thus enhance the cold crystallization of PLA by enhancing the nucleation of PLA; results a decrease in cold crystallization temperature.

Application of PHAs PLA Composites

The composites of PHAs and PLA can advance and extend the applicability of PHAs as well as PLA. Depending on the specific properties required, the composites can be tailor-made to incorporate some extra features or to improve the material properties currently present in particular PHAs and PLA, make a wide application.

The pure PHAs and PLA have some common limitations, such as brittleness, difficult heat-sealing ability, high oxygen and vapor permeability, poor mechanical strength, thermal instability etc. and hamper their applicability. These drawbacks can be overcome by making composites such as PHAs/PLA composites. It is very feasible and versatile in food packaging applications. P(3HB)/PLA: 75/25 wt% composite using polyester plasticizer to create a new type of eco-friendly material suitable for single-use applications, such as fast food packaging (Abdelwahab *et al.*, 2012). Besides food packaging, the PHAs/PLA composites can be used in general purpose such as packaging household items that are a part of daily consumerism. It is a promising material for making kitchen films, cups, coats and sanitary napkins (Reddy *et al.*, 2013).

PHAs/PLA composites are attracting attention for making various electrical and electronic products, such as display panels, sensors and solar cells. These composites can also be used for a large range of products, including, scientific, medical, military and security products (Reddy *et al.*, 2013).

The composites of PHAs/PLA are also applied to medical and biopharmaceutical applications. It plays a vital role in creation of tissue engineering scaffolds and as a material for drug delivery.

However, the properties developed through making composites of PHAs/PLA are more favourable for environmental or food preservation or household applications but limited success in biomedical scenarios. Intensive research is required to improve compatibilizing mechanisms, surface modification and advanced processing techniques to produce novel materials suitable for specific applications mainly in biomedical issue.

Summary

Bioplastics are nowadays attracting a lot of attention due to the growing importance to sustainable development. Polyhydroxyalkanoates (PHAs) and polylactic acid (PLA) are the biodegradable bioplastics that have the potential to substitute the conventional plastics. PHAs are known as a complete bio-plastics; produced by bioprocess using microorganism from renewable

resource. Polyhydroxybutyrate (PHB) has the similar material properties of polypropylene (PP) but PHB is hard to process due to its high melting temperature – limits its application. PLA is produced through a mixed process; lactic acid by fermentation using renewable resource and then to PLA through polymerization reaction. PLA has good mechanical properties particularly, high tensile strength, young's modulus and good flexural strength, which are even higher than those of polystyrene (PS), PP, polyethylene (PE) and/or other conventional polymers. But PLA is very brittle that hamper its wide applications.

Although, both PHAs and PLA are biodegradable and produced from renewable resource, their potential applications are hampered due to the limitations of several properties. These drawbacks could be overcome by producing PHAs/PLA composites. The composites have the improved properties such as miscibility, crystallization, morphology, mechanical properties and degradation behavior. The composites of bio-based polymers not only can replace existing polymers in various sectors but also can provide new combinations of properties and extended its applications. The composition and types of PHAs within the composite have a significant effect on the toughness, miscibility, crystallization, mechanical properties and hydrolytic degradation. Melt compounding, among the different methods for the production of PHAs/PLA composites, is the most suited one due to its high production capacity, environmentally friendly process and better properties of the produced composites. The use of PHAs/PLA composites in various sector such as environmental, food preservation, electronics, packaging, commercial purpose, household applications etc are increasing day by day but still it has very limited success in desired medical application. Intensive research is required to improve the properties of PHAs/PLA composites for the specific application in biomedical issue.

Glossary

ACP	Acyl carrier protein	PET	Polyethylene terephthalate
CoA	Coenzyme A	PHA	Polyhydroxyalkanoates
DCW	Dry cell weight	PHB	Polyhydroxybutyrate
DSC	Differential scanning calorimetry	PHBV	Polyhydroxybutyrate copolymer valerate
EPS	Extracellular polysaccharide	PHD	Polyhydroxy hexadecanoic acid
LDPE	Light density polyethylene	RAF	Rigid amorphous fraction
MCL	Medium chain length	SCL	Short chain length
		T_g	Glass transition temperature

Introduction

In the present era of modern industrialization, numerous sophisticated materials and products with high-end applications are manufactured in large scale employing plastics as raw materials. A view from the lens of sustainability supports the paradigm that bioplastics can be an alternative to the conventional petrochemical-based polymers. The total global bioplastic production capacities are forecasted to stand at 6.1 million tons in 2021, approximately 1.45 times higher than the production capacity in 2016. The biobased durable plastic productions are expected to increase by over 80% in 2019, compared to 60% in 2014 (Fig. 1). Though future prospects highlight the scope for increased bioplastics productions, currently their productions are limited to a mere 1% of the total production volume (300 million tons). Due to increase in demand, the supply of bioplastics is recording a growth of 20%–100% per year with bio-based/non-biodegradable plastics such as biobased Polyethylene and biobased Polyethylene Terephthalate (PET) being the main drivers for this growth.

Fig. 1 Global production capacities 2013–2019 and production capacities of bioplastics by region. Reproduced from Sumathi, S., Chai, S.P., Mohamed, A.R., 2008. Utilization of oil palm as a source of renewable energy in Malaysia. *Renew. Sustain. Energy Rev.* 12, 2404–2421. doi:10.1016/j.rser.2007.06.006.

Fig. 2 Biodegradation cycle of PHAs. Reproduced from Altaee, N., El-Hiti, G.A., Fahdil, A., Sudesh, K., Yousif, E., 2016. Biodegradation of different formulations of polyhydroxybutyrate films in soil. Springerplus 5 (1), 762. doi:10.1186/s40064-016-2480-2.

This trend is supportive in developing regions, where Asia accounts for 58.1% of the total global production of bioplastics. Polyhydroxyalkanoates (PHA), the most researched biopolymers in the present century, are expected to have a production rate of over 1.2 million metric tons by 2019, due to the ramping up of old and new capacities in Asia and the USA.

During the forecast period, the highest growth rate of the projected areas for packaging, chemicals, and biomedical are estimated to encompass the wide application of the PHA copolymer type. This, besides offering similar benefits as other PHA types, manifests cost-effectiveness and thus makes it facultative to lead the global PHA market mainly segmented into Africa, European Union, North America, South America, Middle East, and Asia-Pacific region. The demand for PHA in the key regions of the Asia-Pacific market is projected to grow to the highest by the end of 2021 in light of expected escalated growth in the pharmaceutical, agro-industries, and packaging sectors. Finding innovative ways and processes to produce bio-plastics are the present focus of the research and development segment of companies. The high cost of production relative to the conventional plastics have been the major bottleneck in its growth despite fluctuating oil prices leading to the hunt for stable raw material for plastic production, tax subsidies, taxes on conventional plastics, and government policies for the cleaner environment being major reasons for driving their market.

There has been a search of nucleating agents and plasticizers that are capable of improving the flexibility of the polymer and improve its crystallinity. This confines the focus in compounding PHB as there is inconsistency in its mechanical properties leading to fragility, attributed to its extensively reported recrystallization at room temperature.

PHAs are a class of natural esters secreted by microorganism as intracellular granules under nitrogen limiting condition along with excess carbon source. Around 30% of natural soil microbial flora can produce this polymer with some producing upto 90% of its dry weight. This class of natural esters exhibits high variability by encompassing more than 150 monomer types and weighing up to 100,000 Da (Dalton). The polymer remains amorphous inside the cells due to its stability contributed by phospholipids while it turns crystalline after extraction. Its composition was enunciated by Lemoigne in 1925, though Beijerinck reported its occurrence back in 1888 (De Koning, 1993; Pal *et al.*, 1999). It took several years to recognize PHA as a natural polymer because of refusals from some organic chemists regarding its existence hovered through the scientific community. After successfully establishing its identity as a natural polymer, it took a multidimensional evolution in different fields for various applications such as medical implants, cosmetics, and more importantly as bioplastics used for various packaging applications (Pal *et al.*, 1999).

Production and utilization of synthetic plastics come with a cost for both environment and health hazards. The depleting fossil reserves pose serious constrictions on the large-scale production and consumption of plastics. PHAs can address this problem and also meet consumer demands if produced in large amounts as they are hydrophobic, thermoplastic, biodegradable, and impermeable to gases and water. It exhibits high crystallinity and high melting point when compared to LDPE. These physical properties make it a substitute for conventional plastics. Moreover, PHA producing micro-organisms help in carbon sequestration, by utilizing renewable feedstock, which in turn utilize the atmospheric carbon-di-oxide, following a carbon cycle (Fig. 2).

Fig. 3 Repeating units of the monomer of Polyhydroxyalkanoates. Reproduced from Koller, M., Vadjla, D., Braunnegg, G., Atlic, A., 2017. Formal- and high-structured kinetic process modeling and footprint area analysis of binary imaged cells: Tools to understand and optimize multistage-continuous PHA biosynthesis. *The EuroBiotech. J.* 1 (3), 203–211. doi:10.24190/ISSN2564-615X/2017/03.01.

At the global level, 24 companies produce PHA and the number is expected to increase further. Studies suggest that the demand for bioplastics can shoot up to 20% by 2020. Increasing the PHA production coupled with affordable prices can boost its potential as an alternative to synthetic plastics. This can be done by utilizing cheap carbon sources that can reduce the price of PHA produced at the process end. Some cheap carbon feedstocks that can be utilized for PHA production are lignocellulosic biomass, oils, and glycerol. These low-cost substrates are metabolized in the microorganisms involving various pathways to yield PHA as the end product of the metabolism. Oils follow fatty acid metabolism and beta-oxidation whereas lignocellulosic biomass and glycerol follow different pathways ultimately synthesizing Acetyl-CoA for PHA production.

A wide variety of methodologies are available at different stages of the production process starting from pretreatment of feedstocks to the recovery of PHA from biomass. Pretreatment of biomass is an essential role to obtain the required simple utilizable units for microorganisms to synthesize PHA. For example, enzymatic hydrolysis of starch is required to produce two molecules of a monosaccharide, which is taken up by the microorganism for producing PHAs. Fermentation conditions depend upon the strains being employed in the process along with the physical and chemical properties of the medium. For example, *Cuprividus necator* is the most commonly used microorganism which can grow in both aerobic and anaerobic conditions. After fermentation, the recovery of PHAs from the cells requires special unit operations. Cell disruption, solvent extraction, digestion using a surfactant, and enzymatic digestion are some of the commonly used methods to recover PHAs from cell biomass.

Structure of PHAs

The basic structural backbone of PHAs contains repeating units of aliphatic polyesters (As shown in Fig. 3) ranging from 600 to 35,000 (Albuquerque and Malafaia, 2018).

PHA with $n=1$ represents a class of poly(3-hydroxyalkonates) while $n=2$ represents poly(4-hydroxyalkonates). The type of derivate attached to the side chain (R) of the unit determines the functionality of the monomer. Depending on the number of carbon atoms in a monomeric unit of the chain, PHAs are classified into three types: Short chain-length monomers (3–5 carbon atoms), Medium chain length monomers (6–15 carbon atoms) and Long chain-length monomers (more than 15). The type of PHA produced depends upon the biochemical pathways inherently (or genetically modified) present in the microorganism.

Thermal and Mechanical Properties of PHAs

Despite exhibiting numerous properties like high melting temperature (175°C) and relatively high tensile strength (30–35 MPa) as to petroleum-based polymers (e.g., polypropylene), the curbed usage of isostatic PHB pertains mainly to the narrow processing window of this plastic and its internal brittleness (El-Hadi *et al.*, 2002). The proximity of the glass transition temperature (T_g) of PHB to the room temperature inciting secondary crystallization of the amorphous phase at room temperature has been exhibited by several authors (Steinbüchel, 1991; de Koning and Lemstra, 1993); its low nucleation density, justifying the inter-spherulitic cracks in large spherulites, has been a major antecedents for the brittleness exhibited by PHB and PHB/V.

The rigid amorphous chains coupled with the crystals are expected to be affected by the slow crystallization kinetics of the PHB which is attributed to its homogeneity emanated from the natural origin of the polymer is by tuning the crystallinity level. The homogeneity of PHB rules out the presence of impurities or catalyst residues that can act as heterogeneous nuclei (Di Lorenzo *et al.*, 2001). The heterogeneous nuclei promote crystallization onset by increasing the number of small spherulites, thereby disrupting its crystallization kinetics.

The influence by the physical state of the amorphous layer in contact with the growing crystals on the mechanism of crystallization of PHB was established in a recent study that expounds the crystal growth being hampered by the Rigid Amorphous Fraction (RAF) establishment during the heating of initially amorphous PHB coordinating with crystal formation at the first stage of cold crystallization (Androsch, 2008). This could only proceed on the achievement of complete mobilization of the RAF upon further temperature increase that can also be enhanced by the addition of plasticizers and thus, lowering the glass transition.

Upon quasi-isothermal cold crystallization of PHB at 22.8°C, the quantification of the kinetic vitrification of the rigid amorphous fraction RAF of the amorphous phase that exhibits reduced molecular mobility when connected with the crystalline phase covalently which are reported to be around 20%–30% of the overall sample mass, connoted the establishment of whole RAF of PHB during crystallization (Schick *et al.*, 2002).

In addition to morphology, the lowering of glass transition temperature (T_g) to the testing temperature mitigates higher flexibility and high elongation at break for the formulated/modified PHB. Faster cooling after melting is observed to affect the

nucleation rate and spherulite size, thereby adding to nucleation density and increasing the crystallization rate in the blends. This alleviates crystallinity due to the formation of fine spherulites that is cardinal in achieving central mechanical properties.

As evident from the random chain scission reaction of crotonic acid and various oligomers involving a cis-elimination reaction of β -CH and a six-member ring transition, a severe degradation of the PHB along with the degraded products of olefinic and carboxylic acid and reduction on the melt velocity observed on a short exposure of PHB to temperatures near 180°C, just above its melting point, poses a serious problem in processing of PHB due to a rapid molecular weight decrease with the most common mechanisms (Grassie *et al.*, 1984). The addition of lubricant during the processing at 170–180°C prevents the thermal degradation of the chains and delays crystallization by decreasing the crystallization temperature.

At higher temperatures, random cleavage of PHB chains occurs, decreasing the resultant molecular weight. This can be observed in the Differential Scanning Calorimetry (DSC) data where a bimodal distribution of crystallite size is seen as a double peak (Erceg *et al.*, 2005).

The non-conventional irregularly shaped DSC exotherms under given crystallization conditions characterized by spikes are related to the non-monotonous development of latent heat with a sudden increase and decrease in the crystallization.

Synthesizing copolyesters containing other hydroxyalkanoates groups is one of the main approaches being investigated extensively (Zhang *et al.*, 1997; Ahmed *et al.*, 2010). This process involves a mixture of groups in different molar ratios and is very effective in improving the mechanical properties as it lowers the melting point of the polymer thereby reducing its degradation (Qiu *et al.*, 2005). A decreased processing temperature can be achieved by blending plasticizers with polymers and modifying its physical properties. Thus, PHB is commonly blended with plasticizers and nucleation agents that lead to a lower glass temperature and lower crystallinity as it forms numerous, small and imperfect crystallites.

Synthesis of PHAs

Chemical Synthesis of PHAs

Chemical synthesis of PHA was proposed in 1998 where propiolactones are substituted using aluminum or zinc alkyl catalysts and water being the cocatalyst (Bastioli, 1998). Biodegradable PHBV has been successfully produced from butyrolactone and valerolactone with an oligomeric aluminoxane catalyst and achieved an almost identical resemblance to the biopolymers (Hocking and Marchessault, 1998). The stereochemistry plays an important role in the biodegradability of the polymer and also decides its structural integrity. However, the biologically produced polymers have the same stereochemistry and thereby replacing the highly priced lactone monomer.

Biological Synthesis of PHAs

Lignocellulosic biomass consists of cellulose, hemicelluloses, and lignin. Each of these components follows different biochemical pathways for PHA production. Fig. 4 shows an overview of the biochemical pathways in the production of PHA from different sources. The action of laccase and other enzymes degrade lignin to cinnamate, coumarate, ferulate, and methyl-(phenyl). Except for methyl phenyl, other components are converted to 3-oxodipate following a series of enzyme-mediated conversions. 3-oxodipate is converted into 3-Keto-adipyl CoA, and finally into Acetyl CoA. The biochemical pathway indicates the role of acetyl-CoA for the production of PHB. Degraded lignin products are metabolized by the microorganism to increase the acetyl-CoA concentration, which is further used for the production of PHB. Degradation of hemicelluloses yields xylose, arabinose, mannose, and glucose. Xylose and arabinose produce xylulose-5 Phosphate which is finally converted into fructose-6 Phosphate that enters into glycolysis pathway to generate acetyl-CoA for production of PHB. Mannose is converted to Mannose-6 Phosphate by the enzyme hexokinase. Mannose-6 Phosphate is converted to Fructose-6 Phosphate which further enters into glycolysis pathway. Glycerol kinase and glycerol dehydrogenase convert glycerol into glycerol-3 Phosphate and dihydroxyacetone, which are in turn converted into dihydroxyacetone phosphate that is used for the synthesis of pyruvate. The conversion of fatty acids present in oils to PHA takes place via different biochemical routes. R-3 hydroxylacyl CoA synthesized from beta-oxidation pathway results in the production of P3HA. Production of P(3HB-CO-3HA) SCL-MCL-PHA is achieved through conversion from primary precursor malonyl ACP through a series of steps (As depicted in Fig. 4). When, containing a high amount of lactose is converted into phosphoenol pyruvate to produce PHB via glycolysis pathway. Molasses is a rich source of sucrose that can be converted to glucose and fructose which enters the glycolysis pathway to produce PHB.

Microorganisms

Diverse groups of micro-organism are found to accumulate PHAs under nitrogen depleting conditions (Fig. 5). Both gram positive and gram negative bacteria's were found to accumulate PHAs well. Some common examples include *Rhodobacter sp* (Kim *et al.*, 2011; Gabrielyan *et al.*, 2015; Ali Hassan *et al.*, 1997), *Cupriavidus necator* (Arikawa *et al.*, 2017; Martino *et al.*, 2014; Gahlawat and Soni, 2017), *Bacillus sp* (Chandani Devi *et al.*, 2018; Reddy *et al.*, 2009; Venkateswar Reddy *et al.*, 2014; Singh *et al.*, 2009; Sreekanth *et al.*, 2013; Kynadi and Suchithra, 2017) and *Pseudomonas sp* (Qiu *et al.*, 2005; Liu *et al.*, 2011; Costa *et al.*, 2009; Gumel *et al.*, 2012;

Fig. 4 Overview of the biosynthetic pathway involved in the production of PHAs from various biomass sources. Reproduced from Srirangan, K., Liu, X., Tran, T.T., Charles, T.C., Moo-Young, M., 2016. Engineering of *Escherichia coli* for direct and modulated biosynthesis of poly (3-hydroxybutyrate-co-3-hydroxyvalerate) copolymer using unrelated carbon sources. *Nat. Publ. Gr.*, 1–11. doi:10.1038/srep36470. Mozejko-Ciesielska, J., Kiewisz, R., 2016. Bacterial polyhydroxyalkanoates: Still fabulous *Microbiol. Res.* 192, 271–282. doi:10.1016/j.micres.2016.07.010. Environ. Microbiol.* 75 (14), 4676–4686. doi:10.1128/AEM.02486-08.

Poblete-castro *et al.*, 2014; Soberón-Chávez *et al.*, 2005). With the advent of genetic engineering, a powerful tool to alter the base sequence to impart or enhance a particular characteristic, microorganisms have been mutated to enhance their production capacity. *Pseudomonas sp* is one of the most researched organisms to enhance the production of PHA by using genetic engineering.

Biomass Feedstocks for PHA Production

Industrial Waste

Carbon feedstocks are the basic raw materials utilized by microorganisms as a source to carry out their regular metabolisms. Experimenting with different carbon feedstocks has been a great topic of interest among researchers. Apart from conventional high glucose/cellulose-containing agricultural feedstocks, several industrial wastes are being alternatively explored as well as used at industrial scale for PHA production. Waste effluents from fruit processing industries, paper, and pulp industries and sugar industries are rich in carbon sources that can be tapped by PHA producing microorganisms for efficient conversion to PHA (Pakalapati *et al.*, 2018). Whey produced from the cheese industry was used as a carbon source for the growth of PHA producing microorganism (Oliveira *et al.*, 2017). Several other interesting non-agricultural feedstocks used in PHA production are Biodiesel waste (glycerol) (Ray *et al.*, 2016), municipal solid waste (Korkakaki *et al.*, 2016), food waste (Wen *et al.*, 2018), slaughtering wastes (Shahzad *et al.*, 2017) and waste animal fats (Riedel *et al.*, 2015).

Food Wastes

Two fermented cheese whey's composed of lactic, acetic and butyric acids (FCW1) and acetic, propionic, butyric, lactic and valeric acids (FCW2) were subjected for production of PHA using a preselected mixed microbial culture (MMC) (Colombo *et al.*, 2016). Cassava has an excellent nutritional profile with a high amount of carbohydrates. It can be grown in areas where water stress is commonly making them a preferable option for food industries. Cassava starch wastewater was used for producing PHA from sequencing batch reactor (SBR) treatment system seeded with *Bacillus tequilensis* MSU 112, a PHA-producing bacterial strain (Chaleomrum *et al.*, 2014).

Pseudomonas pseudoflava produced PHA using synthetic wastewater as a carbon source. The carbon concentration was varied from 5 g L⁻¹ to 60 g L⁻¹ and 20 g L⁻¹ was identified as the optimum concentration for PHA production (57%). It produced P3HB when acetate was used as a sole carbon source and produced P(3HB-co-3HV) by addition of propionate as a cosubstrate. Furthermore, PHA synthase was extracted from *P. pseudoflava* and *P. pallero* which are vital for PHA synthesis (Venkateswar Reddy *et al.*, 2017).

MMC was used to produce PHA using hardwood spent sulfite liquor (HSSL) as a feedstock under aerobic dynamic feeding (ADF) conditions. It was found that acetic acid was utilized completely by the consortia leaving behind partially consumed xylose and lignosulphonates (Queirós *et al.*, 2014). Also, there are studies reporting the production of PHA from the organic fraction of municipal solid waste (OFMSW) leachate (Korkakaki *et al.*, 2016).

Biodiesel production units generate a large amount of glycerol as a waste by-product during the transesterification process. Some bacterial strains use glycerol as a carbon source for the synthesis of PHA.

A novel strain isolate named *Pandoraea sp.* MA03 was used for the production of PHA from glycerol. It was found that 10–50 g L⁻¹ of carbon source was found to be the most optimal concentration of carbon source required for maximal production of P3HB (de Paula *et al.*, 2017). *Bacillus sphaericus* NII 0838 exhibited the potential to produce PHB (31%) by utilizing the crude glycerol from biodiesel industry under nitrogen limiting conditions (Sindhu *et al.*, 2011).

Pseudomonas oleovorans was able to produce PHA by metabolizing alkanolic acids from hexanoate to decanoate. The maximum yield of 30% DCW with octanoate or nonanoate was obtained and the molecular weights of PHA produced by this bacterium range from 90,000 to 370,000 (Brandl *et al.*, 1988). Sugar mill waste generates a large amount of molasses and bagasse during sugar production process from cane juice. *Sphingo bacterium sp.* isolates served the dual purpose of decolorizing Direct Red 5B (DR5B) and synthesizing polyhydroxyhexadecanoic acid (PHD) in medium containing a significantly high amount of molasses as a carbon source (Tamboli *et al.*, 2010).

Previously, these industrial wastes were released into the environments, causing environmental pollution with irreversible damages to the surrounding niche. Industrial waste can be sustainably disposed of safely as well as utilized for production of high-value low volume products (Koller *et al.*, 2017).

Algae

Algal biomass can be subjected to degradation using microorganisms for producing simple carbon sources that act as a substrate for PHA production. Microalgae (Ghosh *et al.*, 2019) and *Gelidium amansii* red algae (Sawant *et al.*, 2018) are some of the algal biomass used in PHA productions. *Saccharophagus degradans*, a bacterium used to degrade the *Gelidium amansii* for the production of PHA by utilizing algae as its carbon source. The yield was reported in the range of 17%–27% of P(3HB). *Haloferax mediterranei* was used to produce PHA by utilizing micro-algae as a carbon source. The total production was found to be 2.2 ± 0.12 g/L (Ghosh *et al.*, 2019). Algal biomass has gained popularity in environmental aspects due to their photosynthetic ability. Moreover, unlike agricultural feedstocks, algae do not require farmlands for cultivation. These advantages make algae the most suitable candidate for the production of PHA aided by a microbial consortium.

Vegetable Oils

In the modern world, million tons of cooking oils are being disposed of directly into the wastewater stream. It is reported that around 1 million tons of cooking oils are being generated annually in Europe alone; suggesting that cooked oils can be available around the year without any hindrance in the supply chain. Low-cost factor coupled with high fatty acid contents and conversion ratio with stable supply make cooking oils as a best alternative carbon source for producing PHA, even at industrial scale.

Cooked oils are recognized as the low-cost carbon source with the potential to support the growth of the microorganism. It contains a high amount of unsaturated fatty acids rendering them unsafe for human consumption. This scenario is exactly opposite for microorganism, which metabolizes fatty acids through the beta-oxidation pathway and synthesizes valuable PHA without undergoing any significant inhibitory effects (Riedel *et al.*, 2015). A study reported the production of PHA from waste frying oil with a yield of 1.2 g L⁻¹ equivalent to the yield obtained when pure glucose was used as a carbon source (Verlinden *et al.*, 2011). This suggests that cooking oils can be a cost-effective carbon substrate in the long run. If further research is made to maximize the fatty acids uptake rate by genetically engineering the microorganism, a better yield can be expected. A study reported that a strain of *Pseudomonas sp.* has the potential to produce PHA from vegetable oils with a high propensity for linoleic acids as a carbon source (Tufail *et al.*, 2017). This opens the possibility of research to find or engineer suitable strains capable of selectively depleting the components present in the oils for efficient conversion to PHAs.

Many other oils such as *Calophyllum inophyllum* oils, canola oils, rubber seed oils, and palm oils are utilized for production of PHA. Around 604 mg g^{-1} (On dry weight basis) of PHA was produced using *Bacillus cereus* in the media containing low-cost rubber seed oil (RSO) as a carbon source. The result was obtained based on a full factorial design indicating an optimized RSO of 1.5% (v/v). The total yield was found to be 2.16 g L^{-1} under a growth period of 3 days (Kynadi and Suchithra, 2017). MCL-PHA was produced by *Wautersiae utropha* using fructose as carbon and ammonium sulfate as a nitrogen source. The process was carried out in three stages, starting from batch to fed-batch achieving up to a final cell density to 4.36 g L^{-1} and PHA to 0.36 g L^{-1} respectively. The yield was found to increase from 4.36 g L^{-1} to 18.27 g L^{-1} (with 90% PHA) with the addition of canola oil in the last stage. The presence of 3HV, 3HO, 3HDD, and 3HB were found analytically using ^1H and ^{13}C NMR (López-Cuellar et al., 2011). *Burkholderia* sp. was used to produce 70% and 60% P(3HB) using 0.5% (v/v) crude palm kernel oil and glycerol respectively (Chee et al., 2010). *Calophyllum inophyllum* oil was used for producing PHA using *Cupriavidus necator* by Arumugam and his co-workers and effective value for a carbon source, nitrogen and size of inoculum was studied (Arumugam et al., 2018). A maximum PHA yield of 10.6 g L^{-1} was produced under optimized conditions.

Agricultural Feedstocks and Waste

With the increasing demand for food and fodder due to the population surge, a large amount of agricultural residues are being generated from the agricultural processes. Some commonly generated agriculture wastes are husk, hull, peel, leaves, offals, stem and stalks. At the global level, six main crops such as wheat, rice, soybean, maize, sugarcane, and barely generate 3.7 pentagrams (in dry weight) of agricultural residues on yearly basis (Bentsen et al., 2014). It is estimated that 146,000 kilotons of dry matter can be produced annually in Europe alone (Monforti et al., 2015). Agricultural residues are rich in glucose, sucrose, fructose, cellulose, hemicellulose, starch, arabinose and mannose which can be successfully tapped by microorganism for PHA production. *Haloferax mediterranei*, a halophile, utilized starch, dextrose and whey to produce P(3-HB-co-3-HV), whose composition and the molecular weight was found to be changing depending on the substrates used in the production process. Among the reported yields in the literature, *Halomonas boliviensis* tops the leader board with the capacity to produce a high yield of PHA. Hemicellulosic hydrolysate of sugar maple containing xylose (71.9 g L^{-1}) was used as an inexpensive carbon source to synthesize PHAs using *Burkholderia cepacia*. Fed-batch fermentation resulted in a maximal yield of 8.72 g L^{-1} with 51.4% CDW (Pan et al., 2012). Grasslands covering 30 million square kilometers over the earth possess the potential to act as biomass for PHA production. A fed-batch fermentation of grass juice containing a high amount of mannitol was used as the sole carbon source for the production of PHA using *Burkholderia sacchari*. Under the same experimental setup, *Pseudomonas chlororaphis* synthesized MCL-PHA (Cerrone et al., 2015).

Co-Production of PHA With Other Products

Co-production of PHA with other valuable products have been sought after to create an economic balance under optimized conditions recently. Synthesis of PHB positively induced the accumulation of many other value-added products (Zhang et al., 2006; Liu et al., 2007). Many small molecules that exploit intra and extracellular products such as hydrogen, L-tryptophan, methanol, succinate, amino levulinic acid, and rhamnolipids can be produced. In the context of balancing the *in vivo* metabolism, molecules such as L-arginine, succinate, and L-glutamate are produced. In addition to these features, synthesis of microbial PHA facilitates proper recombinant protein folding (Grage et al., 2011).

Several attempts to coproduce PHA with large molecules mainly α - amylase, recombinant proteins like tissue Plasminogen activator, antibody fusion with PHA proved successful. Shamala and his co-workers produced PHA and α - amylase from unhydrolyzed corn starch supplemented with wheat bran and rice bran using *Bacillus* sp. The PHA produced was 5.9 g L^{-1} and enzyme activity showed to be $2\text{--}40 \text{ U mL min}^{-1}$. Furthermore, Sreekanth and his co-workers studied the carbon to nitrogen ratio of the substrate for producing the enzyme and polymer using the same species. Glucose and sucrose as a carbon source and Yeast extract and ammonium acetate as nitrogen source yielded maximum PHA and α - amylase (Sreekanth et al., 2013).

Several proteins like tissue plasminogen activator and antibodies are expressed with the Phasins and PHA synthases to reduce the purification cost protein loss during downstream processing (Grage et al., 2011; Geng et al., 2010; Barnard et al., 2005; Peters and Rehm, 2005). Extracellular polysaccharides help in the growth and sustainability of cells during adverse growth conditions and nutrient limitation. Lama et al., studied the effect of growth condition on endo and exopolymer biosynthesis in *Anabena cylindrica* in the synthetic medium (Lama et al., 1996). It was reported that 0.3 g L^{-1} of extracellular polysaccharide along with 0.01 g L^{-1} of PHB-co-PHV was produced. Similarly, Pal and his co-workers produced 1.5 g L^{-1} of exopolysaccharides and 2.7 g L^{-1} of PHB using synthetic media (Pal et al., 1999). The coproduction of PHB and EPS was studied in *Ralstonia eutropha* in different glucose and nitrogen concentration. Under optimized condition, 12 g L^{-1} of PHB and 0.1 g L^{-1} of EPS were obtained. Recently Devi et al. (2012) used *Sinorhizobium meliloti* for producing EPS and PHB using rice bran and obtained a yield of 3.6 and 11.8 g L^{-1} of EPS and PHB respectively. *Azotobacter chroococcum* was used for producing EPS and PHB from various carbon sources and was found to produce a comparable amount of PHB and EPS under nitrogen limitation condition (Quagliano and Miyazaki, 1999). Furthermore, *H. boliviensis* and other *Halomonas* species are able to co-produce PHA and osmolytes, i.e., ectoines and hydroxyectoine, in a single process (Quillaguamán et al., 2010).

Alginates find themselves useful in the food and pharmaceutical industries as a stabilizer and gelling agent. Guo and his co-workers produced Alginate oligosaccharides and medium chain length PHA using *Pseudomonas mendocina* in a 200 L fermentor in a medium supplemented with glucose. The yield of 0.57 and 0.316 g L⁻¹ of alginate and PHA was obtained (Guo *et al.*, 2011). Similarly, glycerol was used as carbon source for production of mcl-PHA and alginates using *Pseudomonas mediterranea* and obtained a yield of 6.93 and 0.52 g L⁻¹ of alginate and mcl-PHA respectively. Overexpression of alginate, genes were observed during PHA production.

Pseudomonas aeruginosa has found an important place in co-production of PHA and Rhamnolipids. Coupled production of rhamnolipid and PHA were carried out effectively using variety of microorganisms on substrates like waste glycerol, glucose, decanoate, palm oil, hexadecane, cassava wastewater and waste cooking oil in single stage batch reactors and obtained sizeable yield (Costa *et al.*, 2009; Soberón-Chávez *et al.*, 2005; Hori *et al.*, 2002; Marsudi *et al.*, 2008; Chayabutra and Ju, 2001). Furthermore, owing to its opportunistic pathogenicity there is a quest for the non-pathogenic strain that can utilize complex substrates to produce both the products. Recently, nonpathogenic strains *Burkholderia thailandensis* and *Thermus thermophilus* were used in waste cooking oil and sodium gluconate to yield 60.0% and 34.8% of PHA and 2.2 and 0.2 g L⁻¹ of Rhamnolipid respectively (Kourmentza *et al.*, 2018; Pantazaki *et al.*, 2011). Substrate channelization plays a major role in co-generation of PHA and rhamnolipid as to maintain a balance between fatty acid β – oxidation pathway and fatty acid *de novo* biosynthetic pathway. Rhamnolipid as an extracellular product can easily be extracted than PHA. The rhamnolipid is extracted using a phase separation method and the lower phase containing PHA is extracted using the solvent method as described by Kourmentza *et al.* (2018).

Mothes and his co-workers reported the feasibility of coproduction using glucose and glycerol as substrates. Under fed-batch conditions, the glycerol showed more yield than glucose indicating the complex metabolism involved in the utilization of glycerol by the organism (Mothes *et al.*, 2008). High saline concentration plays a vital role in co-synthesis. A salt concentration of 7.5% yielded a highest ectoine level at 7.3% and 68% of PHB on a weight basis. Further increase in salt concentration, however, lowered the PHA synthesis and increased the ectoine (Guzmán *et al.*, 2009). Chen and his co-workers found that the organism *Halomonas salina* was effective in utilizing monosodium glutamate as a substrate and with an enriched medium, could produce a higher yield of PHB (35.3 g L⁻¹) and ectoine (8.6 g L⁻¹) respectively. Aqueous extraction and recovery of PHB are also optimized to obtain a better yield. This organism is found to utilize all the complex substrates ranging from polyols to sugars, aromatic compounds, and organic acids, proving it to be a potent organism for co-production (Chen *et al.*, 2014a,b).

Co-production of PHA with carotenoids has been an interest in recent years. Among several carotenoids such as astaxanthin, zeaxanthin, β - carotene, adonixanthin, cataxanthin, astaxanthin and aadonixanthin plays a major role in the food and pharma industries. These are much costlier than the normal pigments and hence methods for cogeneration with other products prove to be a better option. Although few reports on dark and photo fermentation on simultaneous production with PHA and hydrogen are available co-productions of pigments are always a topic of interest recently (Eroğlu *et al.*, 2004; Kumar *et al.*, 2018; Ramachandran and Amirul, 2012). Eroglu and his co-workers produced PHA, Hydrogen and carotenoids from *Rhodobacter sphaeroides* cultivated on oil mill wastewater and were able to obtain a yield of 60 mg/L of PHB, 40 mg/L carotenoids and hydrogen. Later large scale cultivation in an 8L photobioreactor by varying carbon sources by Eroglu and his coworkers showed that a satisfactory yield of PHB and carotenoids could be obtained, indicating the feasibility of large-scale co-generation (Eroğlu *et al.*, 2008). Recent works of Kumar *et al.* used glycerol as a substrate to yield astaxanthin (7.14 mg mL⁻¹) and PHB (9.52 g L⁻¹) using a methylotroph *Paracoccus sp.* Using the same species in glucose as a carbon source yielded 0.8 mg L⁻¹ of Astaxanthin and 41% PHA. The downstream process in regard to this organism is found to be very easy as they are known to accumulate carotenoids in the vesicles (Kumar *et al.*, 2018). Combining PHA with hydrogen production is of interest lately. Many types of research have been carried out to optimize the conditions required for simultaneous production of hydrogen and PHA. Under dark and photofermentation, the potential of *Calophyllum inophyllum* oil cake in biohydrogen and polyhydroxyalkanoates production simultaneously using mixed/ cultures of *Enterobacter* and *Rhodobacter* was elucidated by Arumugam *et al.* (2014). High biodegradable organic contents and nutrient-rich compositions made *Calophyllum inophyllum* oil cake as an attractive feedstock for the fermentation process. Higher yield of hydrogen (7.95 L H₂/L) and PHA (10.73 g/L) was observed under alternate dark and photo fermentation compared to complete dark fermentation which could only yield 3.23 L H₂/L and 5.6 g PHA/L collectively. Apart from the normal strains, an attempt was made to use the genetically modified *E. coli* to produced hydrogen and PHA in excess by Wang *et al.* (2012). The photofermentative bacteria are also found to produce hydrogen along with the accumulation of PHA in the presence of excess acetate and butyrate (Kim *et al.*, 2011). These studies show that highly potent bioenergy source hydrogen can also be produced with PHA simultaneously.

Pilot Plant Studies

Production of PHB/PHA at a pilot scale using conventional carbon feedstocks is reported in many studies. *Synechocystis sp.* CCA1A192 was used for the production of PHB in a 200 L tubular photobioreactor semi-continuously for 75 days. In this study, two levels for the cultivation of *Synechocystis sp.* were performed. The first stage lasts for 5–7 days within which the nitrogen source is depleted, a condition that favors PHB production. The biomass production attained 1 g/l containing PHB around 12.5% of cell dry weight under non-sterile conditions (Troschl *et al.*, 2018). Wastewater from ice and milk processing industries were used for the production of PHA in a continuous mode. The process contains a series of reactors namely, the anaerobic acidogenic reactor

(AAR), activated sludge production reactor (ASPR) and PHA synthesis reactor (PHAR). Around 43% of the sludge (on a dry weight basis) contains PHA. The process reduces the volume of disposable sludge as well produce a considerable amount of PHA (Chakravarty *et al.*, 2010). A similar study, using sludge fermentation liquid (containing a high amount of volatile fatty acids) as a carbon source for PHB production was performed using bacterial consortia was done. The PHA content was found to be 59.47% of dry cell weight with a yield of 0.17 gPHA/gCOD (Jia *et al.*, 2014). Concentrate from wastewater treatment plant was used for the production of PHA up to 0.39 gPHA/gVSS (Morgan-Sagastume *et al.*, 2015) and nitrogen removed wastewater gave up to 49% of PHA (In volatile suspended solids) (Bengtsson *et al.*, 2017). Wastewater from candy bar factory was utilized at pilot scale for culturing consortia, mainly containing *Plasticumulans acidivorans*. It produced 0.70 ± 0.05 gPHA/gVSS compared to 0.90 gPHA/gVSS at lab scale (Tamis *et al.*, 2014). A two-stage pilot plant was designed for the production of PHA from olive oil mill wastewater using *Pseudomonas* was achieved with a yield of 25% (Ntaikou *et al.*, 2014). These studies show the real-time pilot scale experiments using wastewater as a potential carbon source for PHA production.

Downstream Processing

Despite the availability of numerous methods for isolation of PHA, such as microbial, enzymatic and plant-based sources, obtaining of maximum yield out of the process still remains a challenge. Several investigations on PHA purification and extraction were carried out recently aiming to optimize downstream process at the industrial scale keeping its composition, purity, and properties as priority parameters (Koller *et al.*, 2013; Fernández-Dacosta *et al.*, 2015; Hajnal *et al.*, 2016). PHA extraction and purification follow two main strategies: solvent extraction and using strong oxidants. In the former method, where a suitable solvent is used to dissolve the cell membrane and other proteins to release the polymer from the cell. Fig. 6 shows an overview of various strategies in downstream processing of PHA. Strong oxidants like acids or surfactants are used to dissolve biomass and separate PHA granules (Kosseva and Rusbandi, 2018).

PHA is recovered from the fermented biomass mainly by digestion (enzymatic or acid), mechanical disruption, compromising the cell membrane during its growth, supercritical fluid extraction and solvent extraction. Digestion dissolves other cell mass, disintegrates the cells containing PHA and conserves the polymer granules. Enzymes, acids and alkali, surfactants and strong oxidizing agents like sodium hypochlorite are widely used for solubilizing non-PHA cellular components (López-Abelairas *et al.*, 2015; Chen *et al.*, 1999). Kim and his co-workers extracted PHB from *Ralstonia eutropha* using sodium dodecyl sulfate surfactant without any pre-treatment steps. 97% of the polymer was extracted without much reduction in the molecular weight of the

Fig. 6 Recovery and purification strategies for PHA from microbial biomass. Reproduced from Koller, M., Niebelschütz, H., Braunnegg, G., 2013. Strategies for recovery and purification of poly[(R)-3-hydroxyalkanoates] (PHA) biopolyesters from surrounding biomass. Eng. Life Sci. 13, 549–562. doi:10.1002/elsc.201300021. Kosseva, M.R., Rusbandi, E., 2018. Trends in the biomanufacture of polyhydroxyalkanoates with focus on downstream processing. Int. J. Biol. Macromol. 107, 762–778. doi:10.1016/j.ijbiomac.2017.09.054.

polymer. Lee *et al.* (1993) used a surfactant palmitoyl carnitine for extracting PHA from *Alkaligenes latus* and *Alkaligenes eutropus* and recorded an extraction rate of 85 and 70% respectively.

Posada *et al.* studied various recovery methods from the glycerol fermentation medium. Among the three methods viz., solvent extraction, combining chemical with surfactant and chemical with enzyme, enzyme alkaline digestion process showed more polymer yield and was also economic (Posada *et al.*, 2011). Lopez and his co-workers evaluated different combinations of treatments for the biomass using chlorinated solvents, alkaline and acid digestions for PHA extraction from *Cupriavidus necator* grown in a synthetic medium. Hypochlorite and dichloromethane treatment yielded higher product purity and a sizeable recovery but acid treatment was preferred considering the polymer degradation, economic and environmental aspects (López-Abelairas *et al.*, 2015). Yu (2008) reported PHA extraction by acid subsequently purifying it with hydrogen peroxide or chloroform with a 97% pure polymer. Studies claimed that the concentration of acid used has a greater impact on the mechanical strength of PHA. Use of Sodium hypochlorite has been attempted by several researchers aiming for a high purity polymer product (Berger *et al.*, 1989; Hahn *et al.*, 1994). Berger and his co-workers used hypochlorite solution to extract polymer from *R. eutropha* and recombinant *E. coli* and obtained purity of 86% and 93% respectively (Berger *et al.*, 1989). Yet another similar study by Hahn *et al.*, yielded 94% of 99% pure PHA from *Cupriavidus taiwanensis* (Hahn *et al.*, 1994).

Mechanical disruption of cell mass to obtain the polymer seems to be an easy and effective method in terms of scale-up, environmental and purity aspects (Tamer *et al.*, 1998). This method can be widely followed in larger scale industrial production having a very less environmental impact, with the only disadvantage having long processing time and sequential treatment (Jacquel *et al.*, 2008). Combining mechanical methods like high-pressure homogenization, ultrasonication with chemical treatments prove a greater recovery than the methods as such (Ghatnekar *et al.*, 2002; Van Wegen and Ling, 1998; Ling *et al.*, 1997).

High-pressure homogenization assisted with an anionic surfactant was used for isolation of polyhydroxybutyrate from the *Methylobacterium sp.* and 95% pure polymer was obtained with a yield of 98% (Ghatnekar *et al.*, 2002). Hwang and his co-workers claimed ultrasonication to be a better method for cellular disruption and PHA separation from the cellular biomass and could attain 80% of the pure polymer (Hwang *et al.*, 2006). Van Wegen and Ling (1998) studied PHA recovery on a large scale using the model suggested by Ling *et al.* (1997). Prior to NaOCl treatment, the biomass was homogenized followed by centrifugation that increased the yield up to 80% recovery. Bead milling was proved to be more effective in recovering PHA from the fermented biomass comparing the high-pressure hydraulic homogenizer (Tamer *et al.*, 1998).

Solvent extraction of PHA is one of the oldest methods used (Baptist, 1962). This method is being preferred widely to suppress the endotoxins and other cellular materials and to yield a polymer with intact structure (Jacquel *et al.*, 2008; Lee *et al.*, 1999). Baptist and his co-workers demonstrated the feasibility of several chlorinated solvents such as chloroform, dichloromethane and methylene chloride to estimate the yield of polymer from *Rhodospirillum rubrum* (Baptist, 1962). Trausnigg and his co-workers used diols, acetalized triols, tricarboxylic acid esters, and lactones to extract PHA from biomass where the highest yield (diethyl succinate- 100% purity) of the polymer was obtained in tricarboxylic acid esters. Kinoshita *et al.* claimed that addition of precipitating solvent to extractant separates PHA crystals with a fluidity more than 97% pure (Kosseva and Rusbandi, 2018). Lee *et al.* (1999) demonstrated effective endotoxin elimination from fermented *E. Coli* biomass while extracting PHA using chloroform indicating the possible use of solvents for gram-negative cellular biomass.

Although the solvents prove to be a convenient method for PHA extraction, it compromises the natural morphology of the polymer and poses a hazard for both the environment and the user at industrial scale. However, this method is suitable in the lab scale owing to the contained environment and scale down approach (Gorenflo *et al.*, 2001). This problem can be overcome by the use of nonchlorinated solvents like ketones, amides, esters, and alcohols at high temperature as claimed by Kurdikar and his co-workers (Kurdikar *et al.*, 2000). The solubility of PHA in different solvent plays a vital role in determining the proper use of solvents for extraction (Terada and Marchessault, 1999).

Owing to exceptional physicochemical properties of the supercritical solvents, they are much sought for the extraction process. Use of carbon dioxide as an extractant was proposed by Castor and his co-workers (Castor and Hong, 1995). Hejazi *et al.*, formulated optimized condition for extraction of PHB (Hejazi *et al.*, 2003). Taking it as a lead, many works that combine the pretreatment process with supercritical extraction process has been proposed (Darani and Mozafari, 2009).

PHA can also be extracted using the fragility of cells where the cells accumulate large fractions of the polymer (Lee *et al.*, 1994; Page and Cornish, 1993). The integrity of the cells are compromised when the PHA is overproduced and on treating the cell mass with either NH_3 (Page and Cornish, 1993), bacteriophage lysis (Fidler and Dennis, 1992) or NaOH (Choi and Lee, 1999), the polymer is recovered.

Economics of PHA Production

The cost of producing PHAs at the industrial scale is mainly based on the cost of fermentation, nature of carbon source, polymer yield from the selected carbon source and downstream processing (Lee and Na, 2013). The cost of the carbon substrate alone tends to contribute to 50% of the total cost (Kim *et al.*, 2000). Based on the use of the polymer in different fields, the cost of downstream processing is also taken into account. High purity products for medical purposes look into more purity than the cost of extraction. While disposable products require cost-effective processing rather than purity of the product (Koller *et al.*, 2013). The extensive study of sustainability of bio-based plastics in terms of environmental and social basis has always been a gap owing to the small number of published studies. Also due to the lack of standardized methods for estimation, there has been less data for estimating

Table 1 The comparison of polyhydroxyalkanoates production from various biomass sources reported in the literature

Authors	Carbon source	Reaction type	Microorganism	Yield
Industrial waste				
Wen <i>et al.</i> (2018)	Food waste fermentation leachate	Anaerobic digestion	<i>Paracoccus</i> sp.	33.40%
Venkateswar Reddy <i>et al.</i> (2017)	Synthetic waste	Sequencing batch reactor	<i>P. pseudoflava</i> and <i>P. palleronii</i>	20 g/L

the Life Cycle Assessment of the polymer. Spierling and his co-workers estimated that 35% of bio-based plastics have already taken over the conventional plastics in terms of Global Warming Potential (Spierling *et al.*, 2018). However, the claim was based only from the average industrial data and lacks all the highlights of both plastics.

Large-scale production of biobased plastics faces a major setback from inadequacy of large volume feedstock that is cheap and readily available. Levett and his co-workers studied PHA production from methane and evaluated the economic design for the production of 100,000 tons per annum of PHB from methanotrophic fermentation. Reduction in the cost of feedstock for production was observed from 30% to 50%. Cost of production was reduced in case of thermophilic conditions that could be a potential novel method for producing PHB. The cost of the polymer was in range from 4.1 to 6.8\$ kg⁻¹ of PHB (Levett *et al.*, 2016). Sagastume *et al.* studied the production of PHB using mixed microbial culture from the municipal waste water treatment plant based on mass and energy balances. The model was evaluated for four configurations among which the integration of PHB production with biogas yielded a stable polymer production (Morgan-Sagastume *et al.*, 2016). Leong and his co-workers concluded that aqueous two phase extraction method was best in terms of economical and environmental aspects consuming upto 5.77.

USD Kg⁻¹ of PHA (Leong *et al.*, 2017). Shahzad and his co-workers studied PHA production from waste streams of animal processing industry. It was estimated that 1.41–1.64 £ Kg⁻¹ of PHA was produced from high protein content offal. The transportation cost was about 61 tons of waste biomass and with the input cost of 13.88 million Euros per annum for PHA, the total revenue was 67.5 million Euros per annum (Shahzad *et al.*, 2017). Suwannasing *et al.* (2015) compared pineapple and sugarcane waste as raw material for producing PHA from *Bacillus* strain and claimed pineapple waste to be a better source for polymer production. Furthermore, the substrates did not contain any inhibitors and sugar content was found to be simple. However, they failed to perform a detailed cost analysis in the industrial scale (Suwannasing *et al.*, 2015). Fernandez and his co-workers performed techno-economic analysis on PHB production from waste water and compared three downstream process involving solvent, alkali and hypochlorite treatment. Alkaline treatment found to be most promising in terms of economic and environmental aspects (Fernández-Dacosta *et al.*, 2015). Table 1 summarizes the reports on polyhydroxyalkanoates produced from various carbon sources.

Conclusion

Increased food and fuel demand due to ever growing human population has led the world to look for an alternative to plastics. Conventional plastics derived from petroleum tend to cause pollution with the risk of survivability. Hence, an alternative that solves pollution hazards and mitigates the demand for polymer is of current interest. The production of PHA in sustainable manner is still a burgeoning field where plethora of ideas for parameter optimization and cost cutting strategies are available. Though the methods listed in the chapter are available for producing PHA through an ecofriendly manner, the production cost, raw material expenses and the nature of downstream processing plays a vital role in its side chain grafting and material strengthening. The utilization of the well-defined carbon rich substrates calls for its careful choosing such that the food versus fuel conflict should be resolved. In other words, the substrates should not contain any components that are edible and nutritious. Also, the substrate chosen should be perennially available. Several wastes from fruits, agro industries, offals (Intestinal part of dead meat) and kitchen are used extensively for combined production of PHA and other value added products. Adding to this, the sewage wastes are also extensively used for PHA production. Their ecofriendly nature and flexible modulation properties have put PHA research on a pedestal. Current trend mainly involves producing PHA from defined bacterial cultures and enriched medium that require a lot of process monitoring and control protocols. This results in higher cost of the polymer production alone excluding its polishing process. Technically, downstream processing and increasing the durability of the polymer for public usage makes it even more inaccessible financially. Entry of PHA into the market on a larger scale depends on materials and methods that are economically feasible, socially acceptable and environmentally viable. Through optimizing the bacterial accumulation of PHA, using mixed culture process with low cost substrate and reducing the polishing cost to highly functional polymer, the market demand of PHA can be increased over conventional polymers. The scientific fraternity and industrialists should move hand in hand towards promoting a sustainable way for production of bioplastics.

Conflict of Interest

The authors declare no conflicts of interest.

Introduction

In this natural world, polymers have been found everywhere, since the beginning of time. It is one of the highly functional materials, which forms an inextricable part of human civilization. Generally polymers are light-weight but possess excellent mechanical properties, environmentally superior, renewable, inexpensive and can be easily processed by different methods. Nowadays, polymers are commonly used in thousands of products as foams, clothing, adhesives, fibers, molding, composites, films, plastics, biomaterials, etc. Current applications extend from pharmaceutical, medical, electronic, chemical, health and food industries. More recently, significant developments have occurred in the area of flexible electronic devices based on the useful piezoelectric, semiconducting, optical and electro-optical properties seen in some polymers.

Polymer, a chain like macromolecule, consists of a sequence of various types of monomer units. There can be infinitely many types of polymers depending on the combination and sequence of those monomer units along the chain. The classification of polymers is given in **Table 1** (Sabbatini, 2014; Raju and Kumar, 2016; Robert and Rawn, 2015).

Polymers From Renewable Resources (PFRR)

Polymers from renewable resources have received greater attention over the past two decades. Increasing environmental compatibility, providing additional income to those involved in agriculture and realization of global petroleum resources are finite, have given significant opportunities for improved materials from renewable resources with enhanced support for global sustainability. Biodegradability is an additional benefit of polymers that are degraded and catabolized, eventually to CO₂ and H₂O, by naturally occurring microorganisms such as bacteria, fungi or algae. In addition, when they are degraded, these polymers should not generate any substances that are harmful to the natural environment. At present, high performance plastics, one of the major environmental pollutants around the world, are the outcome of continuous research over the last few decades. The real challenge of renewable polymers lies in finding application, which will result in man production research and price reduction. This can be attained only by improving the end performance of environmental friendly polymers.

Table 1 Classification of polymers

S. No.	Classification	Types of polymers	Examples
1.	Based on origin of source	1. Natural 2. Synthetic 3. Semi Synthetic	Rubber, Wool, Cellulose, Starch and Proteins Nylon, Terylene, PVC, Bakelite, Teflon Cellulose acetate, cellulose nitrate
2.	Based on Structure	1. Linear 2. Branched 3. Cross-linked 4. Network	HDPE, Nylons LDPE, LLDPE Bakelite, Melamine, Formaldehyde resins Epoxies, polyurethanes and phenol-formaldehyde
3.	Based on Molecular Forces	1. Elastomers 2. Fibers 3. Thermoplasts 4. Thermosets	Natural Rubber, buna-S, buna-N, neoprene Cellulosic, animal and synthetic fibers Commodity Plastics (LDPE, HDPE, PVC, PP) Engineering Plastics (Poly acetol, poly carbonate) Epoxy, Urea Formaldehyde, ABS,
4.	Based on method of synthesis	1. Addition or chain growth 2. Condensation or step growth	Polyethylene, Polypropylene, PVC, Teflon Polyamides, Polyesters
5.	Based on backbone of polymers	1. Organic 2. Inorganic	Hydrogen, Oxygen, Nitrogen Glass, Silicon rubber
6.	Based on difference in configuration	1. Isotactic 2. Syndiotactic 3. Atactic	Polypropylene Guttapercha Polyvinyl chloride
7.	Based on composition	1. Homopolymers 2. Copolymers	Polyethylene, Polypropylene, Nylon 6 Nylon 6, 6
8.	Based on atoms	1. Homochain 2. Heterochain	Polyethylene, vinyl polymers, polyacetylene Polyethers, polyesters, polyamides
9.	Crystallinity	1. Crystalline 2. Amorphous 3. Semi-crystalline	HDPE, LDPE, cellulosic fibers Synthetic rubbers, poly (vinyl acetate), polystyrene Polybutene, Gutta percha (1, 4 trans polyisoprene) etc.

Classification of PFRR

PFRR can be classified into three groups: they are (i) the natural polymers most commonly available are extracted from marine, agricultural animals and plants. Examples are polysaccharides (cellulose, starch, chitin, pectin, natural gums), proteins (collagen, soy, whey, casein), polyisoprenes, etc., (ii) polymers produced from chemical synthesis from bio-derived monomers such as polylactic acid (PLA), propanediol; and (iii) polymers produced directly by natural or genetically modified bacteria such as polyhydroxyalkanoates (PHA), dextran, xanthan, gellan, etc.

In this article, polymers from renewable resources such as PLA, PHA and polysaccharides, in particular those which have been used as or have been shown to have potential for use as polymeric materials are briefly reviewed. Physical properties of polymers include molecular weight, density, degree of polymerization, crystallinity of material and so on. Chemical properties such as solubility and permeability, thermal properties like melting, glass transition, crystallization temperature were discussed. Life cycle assessment (LCA) is a powerful and valuable tool for measuring the environmental optimization of the products which was taken into the account as the end-of-life options such as landfills, incineration, composting and recycling.

Polylactic Acid (C₃H₄O₂)_n

Poly lactide or PLA is a kind of biodegradable, hydrolysable aliphatic polyester, commodity polymer derived from 100% renewable agricultural resources such as corn starch, tapioca roots, cassava roots or sugarcane. It has a potential industrial application as packaging materials and also a leading biomaterial for numerous applications in medicine such as controlled drug delivery systems, surgical sutures, bone tissue engineering scaffolds (Chaozong *et al.*, 2004) and healing dental extraction wounds. PLA has stereoisomers of D-Lactic (produced by microorganisms) and L-Lactic acid (natural and biologically important isomer). The major limitation of PLA is the low molecular weight (M_w), which was first synthesized by Wallace Carothers in 1932. Later he developed the high M_w PLA by preferring the ring opening polymerization process (ROP). Various methods could be adopted to prepare PLA, which includes polymer through lactide formation, ROP and DCP (direct condensation polymerization process like azeotropic dehydration and enzymatic polymerization). Extrusion, casting, injection molding, thermoforming and fiber spinning are the different methods to prepare PLA into useful and versatile products (Lim *et al.*, 2008). The production of PLA has number of advantages compared to other polymers. The advantages are a) ecofriendly b) biocompatibility c) processability d) significant energy savings e) improvement of farm economy f) reduction of landfill volumes g) fixation of significant quantities of CO₂, the leading greenhouse gas (Dorgan *et al.*, 2000). On the other hand, this polymer has some drawbacks like, a) poor impact resistance, b) slow degradation rate c) moisture sensitivity, d) lack of reactive side chain groups and relatively expensive.

Properties of PLA

The characteristic features of PLA closely resemble polystyrene and are comparable to many petroleum based products; PLA produces an excellent ecofriendly polymer during polymerization. The physical, thermal and mechanical properties of PLA and its copolymers are very dependent on the molecular weight, M_w distribution, and composition. Generally the properties of composites are greatly influenced by the crystallinity of PLA used. The structure of PLA was shown in Fig. 1 (Aliotta *et al.*, 2019).

PLA is very clear and colorless thermoplastic which is soluble in dioxane, chloroform, acetonitrile, methylene chloride dichloroacetic acid etc. At the same time, it is not soluble in water, some alcohols and alkanes. The density of amorphous and crystalline PLLA has been reported as 1.248 kg L⁻¹ and 1.290 kg L⁻¹, respectively. The density of solid PLA was reported as 1.36 g cm⁻³ for L-lactide, 1.33 g cm⁻³ for meso-lactide, 1.36 g cm⁻³ for crystalline and 1.25 g cm⁻³ for amorphous PLA, respectively (Auras *et al.*, 2004). Moreover, PLA specimens sinks in a liquid column, has the density of 1.240 ± 0.002 kg L⁻¹ for poly (98%) L-lactide and 1.243 ± 0.002 kg L⁻¹ for poly (94%) L-lactide.

The thermal properties of PLA were determined by Ahmed *et al.* (2009) based on the number of average molecular mass (M_n) and the nature of the isomer. Glass transition temperature (T_g) and degree of crystallinity ($\chi_c\%$) was increased as a function of M_n . The melting temperature (T_m) and enthalpy (H) of L isomer increased, as M_n was increased from 1100 to 27,500. No crystallization peak was observed in lower M_n range from 550 to 1400. Auras *et al.* (2004) observed that PLA films undergo an endothermic curve superimposed on T_g during the first scan of DSC heating. A relaxation enthalpy of 1.4 Jg⁻¹ for PLA (98%L-lactide) and 2.9 J g⁻¹ for (94%L-lactide) is noticed resulting a secondary molecular reordering in the amorphous phase of

Fig. 1 Structure of PLA.

semi-crystalline polymers. Moreover, *Tabi et al. (2010)* used different temperatures (60–140°C) and time intervals (10–60 min) for the investigations of crystallization of injection molded amorphous and pure PLA specimens in a vented oven. It was verified by wide angle X-ray diffraction (WAXD) spectrometry and the results predicted that the un-annealed PLA had no crystallinity, but one significant peak appeared at 16.3° for the specimens annealed at 80°C. Also the intensity of the peak increases as annealing time increases. The WAXD results showed that in an annealing temperature range of 100–140°C, 10 min were enough to achieve as high crystallinity, as possible for injection molding grade PLA (crystalline content around 40%). The DSC results showed a significant exothermic peak in the temperature range of 80–140°C which is related to cold crystallization. The exothermic peak decreased with increasing crystallinity, thus no exothermic peak could be observed for the fully annealed specimens (specimens with around 40% crystalline content).

The melt behavior (Pseudoplastic, non-Newtonian behavior) of PLA is similar to the polystyrene. Semicrystalline PLA has a higher shear viscosity than amorphous PLA at these elevated temperatures (150°C and 170°C) and at various shear rates (30, 50, 70, 90, 110, 130 and 150 rpm screw speeds). The decrement in shear viscosity is noticed for both this type of PLA, as the temperature increased (*Fang and Hanna, 1999*). Melt viscosities of high M_w PLA were reported as 5000–10000 poise (500–1000 Pas) at 10–50 s⁻¹. The average molecular weight of PLA used for injection molding was around 100,000 Daltons and approximately 300,000 tons for cast-extruded film grades (*Garlotta, 2001*).

PLA has an approximate tensile modulus (TM) of 3500 MPa, a maximum tensile strength (TS) of 50 MPa and a low elongation at break of 4% (*Jacobsen and Fritz, 1999*). An improved TM and TS has been obtained with the crosslinking of PLA via the chemical treatment by adding small amount of triallyl isocyanurate and dicumyl peroxide (*Sen-lin et al., 2008*). The mechanical properties like tensile strength, elastic modulus and elongation at break for poly (98%L-lactide) were 72 MPa, 2.11 GPa and 11% respectively, and for poly (94%L-lactide) it was 84 MPa, 2.31 GPa and 7.8% respectively. The higher content of L-lactide present in the PLA film contributes a higher tensile strength. Both PLA films have lower mechanical characteristics, when compared to polyethylene terephthalate (PET), under the same testing conditions.

The CO₂ permeability coefficient of PLA has lower value of 2.77 ± 0.05 for poly (98%L-lactide) at 25°C and higher value of 15.65 ± 0.63 for poly (94%L-lactide) at 45°C. The permeation activation energy, calculated by using Arrhenius equation, has lower value for poly (98%L-lactide) resin. Similarly a significant increase in the O₂ permeability coefficient was noticed as the temperature increases in the range of 5°C (3.5×10^{-18} kgm m⁻² s⁻¹ Pa⁻¹) to 4°C (11×10^{-18} kgm m⁻² s⁻¹ Pa⁻¹) at 0% relative humidity. As water activity level ($A_w = 0.9$) increases, there is a reduction in the O₂ permeability coefficient of 8.2×10^{-18} kgm m⁻² s⁻¹ Pa⁻¹ at 40°C. Nitrogen barrier properties of PLA films are 1.21×10^{-17} kgm m⁻² s⁻¹ Pa⁻¹ with activation energy of 11.2 kJ mol⁻¹ at 30°C.

End-of-Life of PLA

The most economic and feasible method for handling municipal solid waste (MSW) is landfilling. It has lot of environmental impacts primarily due to gas and leachate formation, including health hazards, fires and explosions, vegetation damage, unpleasant odors, landfill settlement, ground water pollution, air pollution, and global warming. The major disadvantage of disposing plastics in landfills lied in the fact that most plastic materials do not degrade in a practical period of time and end up accumulating. Landfills usually do not provide the appropriate environment to promote degradation, and their conditions vary considerably by geographical locations. On the other hand, PLA biodegradation is highly dependent on temperature and moisture since these two factors promote hydrolysis of the polymer chains, and in turn accelerate biodegradation. At mesophilic temperatures little or no degradation of PLA is observed.

Composting provides a viable option for recovering waste packages by returning them to nature. Biodegradability of these biodegradable polymers in composting conditions and soil burial condition are affected by two factors: i) exposure conditions (water or moisture, acidity, temperature, aerobic or anaerobic, enzyme specificity) and ii) polymer factors (polymer structure, chain flexibility, crystallinity M_w , copolymer composition, size and shape). Commercial Composting (CC) or municipal composting is a faster process than backyard or home composting as it managed more intensively and optimal conditions are maintained. For commercial composting, three types of waste are used: a) Yard waste: vegetative waste from leaves, grass, clippings, tree trunks and pruning wastes, b) Food waste: uneaten food or waste from domestic, commercial or institutional sources such as restaurants or cafeterias (*Rynk et al., 1992*), and c) Manure waste: waste from fecal and urinal excretion of livestock and is usually rich in N₂. Commercial composting is a large scale operation, which generally employs turning and active aeration, except for static pile (*Matthew and John, 2018*) and some in-vessel composting system, whereas, home composting is a small scale using small piles or composting bins, usually occurs at lower temperatures. Yard waste and food waste were going into this system, but improper management of food scraps can cause odors and attract unwanted insects or animals. The conversion of organic matter into compost may take 2 years but manual turning can decrease this time to 3–6 months (*EPA, 2006*). This composting are either can be open or closed cylinders revolving drums or orbs that can be rolled along the ground to turn the pile.

Kale et al. (2007) determined the rate at which 473 ml PLA bottles with and without caps (HDPE) and polypropylene (PP) labels decomposed in an industrial compost pile. A 94% of reduction in mass and molecular weight is noticed at the week 2. PLA bottles alone decomposed completely by week 4 while bottles with the caps and labels decomposed are at the week 8. Within 35–45 days, PLA bottles can be composted with the caps and labels (barrier of biodegradation). From their results it was concluded that, in order to reduce the municipal solid waste, a proper infrastructure should be put in place to allow large scale

composting of PLA. Similarly PLA bottles biodegradation tests were carried out in real and simulated (Cumulative Measurement Respirometric, CMR and Gravimetric Measurement Respirometric, GMR) composting conditions. During these two conditions day to day observations were recorded by [Kale et al. \(2007\)](#). With a small increase in M_w (+11, 400 Da), changes in shape and color was noted in the very first day. On the 15th day, a few pieces of bottle were seen, after that no bottle residues could be located through visual inspection. M_w of 4100 Da was obtained on the 30th day. PDI was reduced from 1.84 to 1.04 due to the polymer fragmentation. At the end of the 58th day, the mineralization was $84.2 \pm 0.9\%$ and $77.8 \pm 10.4\%$ respectively for both CMR and GMR systems, which showed similar trends on biodegradation of PLA bottles. The variation in degradation time frame between these two composting conditions (CMR and GMR) depends upon many variables such as size of the polymer sample, sample/compost ratio and nature of the compost material.

A natural way of recycling the polymer is biodegradation and it takes place in two steps: primary biodegradation where the fragmentation of the polymer chain occurs due to hydrolyzes (CO_2 and H_2O) and ultimate biodegradation where the microorganisms assimilate the low M_w chains formed. Recycling is the process of recovering waste or reprocessing the material into new and useful products. Even though PLA is a biodegradable polymer and thus supposed to finish its life in compost, it was interesting to analyze its recyclability. Lack of suitable infrastructure for sorting, recycling and composting these products at their end-of-life are the major constraints. The four level waste management hierarchy (1) source reduction (reuse), (2) recycling (including composting), (3) combustion and (4) disposal through landfill were introduced by European Commission and US Environmental Protection Agency (EPA). Among 100% PLA waste generated mostly from plates, cups, packaging and other durable goods, only a negligible amount i.e., 10% was recovered through recycling and composting. Mechanical recycling (MR) involves recovering, sorting, regrinding and reprocessing the waste PLA. According to [NatureWorks \(2009\)](#), near infrared or black light illumination technology is used to facilitate the sorting of PLA from the waste stream. Due to the contamination of this stream, PLA can be successfully recycled in the current plastics recycling infrastructure. The eminent and inexpensive disposal route to recover the post-consumer PLA is by mechanical recycling. A commercial grade of PLA undergoes melt processing and compression molding methods. Then it was subjected into two different recycling processes. The first process is accelerated aging and melt processing, while the other is accelerated aging, washing and second melt processing step. A decrease of intrinsic viscosity and molecular weight was noticed for PLA. This is because the generation of shorter polymer chain as a result of degradation of PLA during ageing of the polymer. Chemical recycling, a complex and expensive process, where the PLA is hydrolyzed at a high temperature to yield lactic acid, can be readily polymerized to high M_w PLA. Thus if there are sufficient PLA containers entering the waste stream, recycling entrepreneurs may explore means of recovering and recycling PLA in a cost effective fashion.

Polyhydroxyalkanoates (PHA)

A family of biodegradable polyesters is produced in microorganisms as intracellular storage compounds of energy and carbon nutrient deficiency (lack of Nitrogen, phosphate, sulfur, potassium, tin iron, magnesium and carbon). Beijerinck in 1888 (reported in [Chowdhury, 1963](#)) first observed the occurrence of PHA as granules of 0.2–0.5 μm in the bacterial cells, which are 100% biodegradable. Later, it was described as homopolymer containing 3-hydroxybutyric acids (3-HB) by French bacteriologist [Lemoigne \(1926\)](#). The structure of PHA ([Jiang et al., 2016](#)) is shown in [Fig. 2](#).

Production of PHA involves three steps: (i) preprocessing of biomass into reduced sugar, which are easily fermentable in a nutrient broth (ii) optimization of the fermentation process and (iii) extraction and purification of PHA through cell lysis. 250 different microorganisms are reported to produce PHA, out of these, very few microbes have been studied for industrial production. PHAs are natural, biodegradable, non-toxic, hydrophobic, optically active, biocompatible, and synthesis from renewable resources. Due to this behavior, it has a wide range of applications in various fields such as drug delivery, tissue engineering, surgery, wound dressing, water resistant coatings on cardboard or paper, and additives in cosmetics and in food processing industries. Based on the number of C_2 atoms present in the monomer units of PHA, it is classified as (i) short chain length (scl) consisting of 3–5 carbon monomers obtained from bacteria such as *Cupriavidus necator* and *Alcaligenes latus* (ii) medium chain length (mcl) consisting of 6–14 carbon atoms obtained from *Pseudomonas Putida* and *Pseudomonas Mendocina* and (iii) long chain length (lcl) containing more than 14 carbon atoms obtained from *Shewanella oneidensis* and *Aureipira Marina*. The typical examples of scl PHAs are poly 3-hydroxybutyrate (PHB), poly (3-hydroxyvalerate) (PHV) and their copolymers poly (3-

Fig. 2 Structure of polyhydroxyalkanoate.

hydroxybutyrate-co-3hydroxyvalerate) (PHBV). Similarly mcl PHAs have poly 3-hydroxyhexanoate (P3HH₆C₆), poly-3-hydroxyheptanoate (P3HH₇C₇) and poly-3-hydroxyoctanoate (P3HOC₈) etc. The commercial name of PHB is Biogreen and Biomer, and for PHBV it is Biopol. Several methods such as batch, fed-batch and continuous process could be adopted for the production of PHA. Unfortunately, there is a constraint of the production of PHA because it needs special microbial growth condition and expensive raw materials such as the microorganisms, culture condition, fermentable process etc. PHB, the most commonly seen polymer in PHA was first characterized by French Microbiologist Lemoigne (1925). Maximum production of PHB (46.2% per mg cell dry matter) was obtained by *Bacillus Megaterium* strain using sugarcane molasses (2%) and corn steep liquor as sole carbon sources (Gouda *et al.*, 2001). PHA copolymer of PHB/HV with a 3-hydroxyvalerate content of about 11% may have an optimum balance of strength and toughness for a wide range of possible applications (Pachence *et al.*, 2007). The application of PHAs includes as (i) an environmental remedy for packaging industries and biofuels (ii) valuable industrial raw material for synthesis of drugs and chiral compounds, protein purification and (iii) biomedical application for skin, tissue, heart valve, nerve, bone cartilage engineering, therapeutic as implant material regenerative medicine (Masood *et al.*, 2014).

Properties of PHA

The properties of the PHA polymer varied depending on the growth conditions (inoculum, microbial), bacterial strains used for fermentation, optimization of the purification process and carbon source. PHAs are water-insoluble but soluble in halogenated solvents such as chloroform, dichloromethane or dichloroethane, ethyl acetate or methyl tert butyl. The M_w of these polyesters can range from tens into the hundreds of thousands (Pachence *et al.*, 2007). Using Sterical Exclusion Chromatography SEC, the M_w of raw PHA were found between ranges from 2.9 to $604 \times 10^5 \text{ g mol}^{-1}$ and the poly disperse index PDI ranges from 1.52 to 2.53 respectively. The densities of crystalline and amorphous PHA are 1.26 and 1.18 g cm^{-3} respectively. The PHAs become highly crystalline (range of a few to 70%) and shows material properties similar to polypropylene (PP), polyethylene (PE), polystyrene (PS). Normally, the production of PHAs is carried under moderate temperature range of $30\text{--}35^\circ\text{C}$ and at pH $6.5\text{--}7.0$.

PHAs structure is composed of a monomer of 3-hydroxyalkanoic (HA) acid. The general formulae of the monomer unit is $[-O-CH(R)-CH_2-CO-]$. The (R)-3HA monomer units are all in the *R* configuration due to stereospecificity of polymerizing enzyme PHAs synthase. PHAs are resistant to hydrolytic degradation, exhibit a high degree of polymerization ranging from 10^5 to almost 10^7 Da. Short chain length PHA such as PHB are isotactic in structure, with a T_m of $\sim 75\text{--}180^\circ\text{C}$, T_g of $\sim 4^\circ\text{C}$ and crystalline temperature (T_c) $\sim 102\text{--}106^\circ\text{C}$ respectively. The mechanical characteristics exhibit a higher tensile strength at $\sim 43\text{MPa}$ and are highly brittle and stiffer with $\sim 5\%$ reduction in elongation at break. Medium chain length (mcl) PHA is flexible and elastic, having low tensile strength, low crystallinity, low temperatures (T_m , T_g) and higher elongation at break. Depending on the branched length of the hydroxyalkanoic (HA) acid or from the distance between the ester linkages in the polymer backbone, the mechanical properties of PHA ranges from brittle to flexible, and elastic. Typically, PHAs with short pendant groups are hard crystalline whereas longer pendant are elastomeric. In contrast to other polymeric materials, PHB possesses excellent natural resistance to UV weathering but far inferior solvent resistance. Using diluted solution viscometry, the average viscosity molecular weights (M_v) were determined and the value was around 110 kDa . Here the chloroform is used as a solvent. The intrinsic viscosity is $\eta = kM_v^\alpha$, where $k = 1.21 \times 10^{-4}$ and $\alpha = 0.75$ (Thara and Shawapun, 2010). The neat PHBV exhibit a non-Newtonian flow profile and zero shear viscosity is 1990 pa s . Water contact angle (WCA) is an important parameter to measure the work of adhesion, surface tension and interface free energy. The polymer P (3HB) has the highest value of WCA (70.0 ± 0.4) and interface free energy (7.9 erg cm^{-2}) whereas the copolymers P (3HB-co-3HV), P (3HB-co-3HH) and P (3HB)c-4HB have the lowest values. The surface tension (43.1 erg cm^{-2}) and work of adhesion ($112.0 \text{ erg cm}^{-2}$) are higher for P (3HB-co-4HB) (Volova *et al.*, 2013). Wide angle X-ray scattering (WAXS) analysis was used to determine the crystalline structure and crystallinity index of the PHBV. Two strong diffraction pattern peaks located at $2\theta = 13.5^\circ$ and 17° were observed corresponding to the (020) and (110) planes of orthorhombic unit cell and small peaks at $2\theta = 20, 25.5, 27$ and 30.4° . The crystalline index for PHBV is 47.8% , calculated by using the formula $CI = \frac{I_c - I_a}{I_0} \times 100$ where I_a is the area of the amorphous peaks and I_0 is the total intensity. Oxygen barrier properties of PHA were $23\text{--}29$ (O_2 in cc-mil ($100 \text{ cm}^2 \text{ day}^{-1}$) at 25°C $0\% \text{ RH}$) and water barrier was $5\text{--}19$ (in g-mil ($100 \text{ cm}^2 \text{ day}^{-1}$) at 38°C , $90\% \text{ RH}$). These properties and better environmental performance create a bright future for PHA and expected to be a good candidate to substitute PP and PE, but also PET in certain applications.

End-of-Life of PHA

Biodegradation was measured for PHA when it was exposed to aerobic (ASTM 5338), anaerobic (ASTM 5511), marine (ASTM 6691), soil burial (En 13432) and industrial (ASTM D6400) composting conditions. ASTM represents the Standard Test Method for determining the environmental conditions used. PHAs are fully biodegradable in both aerobic and anaerobic, whereas a slower rate in marine environmental conditions was observed. (Joseph, 2018). The biodegradation of PHB and PHBV were evaluated by the loss of mass, tensile strength and roughness of the polymer. Both PHB and PHBV showed biodegradation in soil composting medium at 46°C and at room temperature 24°C respectively (Rosa *et al.*, 2004). After aging in soil composting for 86 days, PHB and PHBV showed a decrease in tensile strength at break (76% for PHB and 74% for PHBV). Weng *et al.* (2011) studied the PHAs with different copolymer content ($40 \text{ mol}\%3\text{HV}$, $20 \text{ Mol}\%3\text{HV}$, $3 \text{ mol}\%3\text{HV}$ and $40 \text{ mol}\%4\text{HB}$) under controlled composting conditions in accordance with ISO 14855-1. The decrease in thermal stability and MW was noticed and

the chemical structure of PHA was unchanged. The order of biodegradability was as follows: P (3HB-co-40mol%4HB) > P (3HB-co-40mol%3HV) > P (3HB-co-3mol%3HV) > P (3HB). Proper management of municipal solid waste (MSW) is an important parameter for environment and economic issues. Approximately 250 million tons of MSWs are generated in USA and only 85 million tons of these materials are recycled or composted (US EPA, 2011). About 55% of MSW is deposited in landfills and about 13% is incinerated (Barlaz *et al.*, 2010). Landfills, a significant source of greenhouse gas emissions and require a lot of land. Incineration of MSW generates air pollutants as well as and a lot of ash requiring landfilling as hazardous waste. The conversion of MSW into paperboard, wood, yard trimmings, food scraps contain biodegradable organic matter. Furthermore, 53% of MSW can be transformed into valuable products instead of landfilling or incineration. Zaverl *et al.* (2012) determined that there was some loss of M_w and mechanical properties when it went through mechanical recycling. The reprocessing cycles did not significantly affect the properties of PHBV (up to 5 cycles). After reprocessing, the mechanical properties were maintained for 4 cycles; however they showed a slight decrease after the fifth cycle (7.1%). Also a slight decrement in M_w by GPC and a drop were noticed after the 3rd, 4th and 5th cycles (8.7%, 13.5% and 16.6% respectively). Chemical recycling has been tried for other biopolymers as well. The chemical recycling of PHAs by thermal degradation resulted in transformation into vinyl monomers, and enzymatic transformation into an oligomer has been reported by Azadeh and Ignacy (2013).

Polysaccharides ($C_6H_{12}O_6$)

Polysaccharides (also known as Glycans) are complex, high molecular weight biological molecules that are almost pure carbohydrate. It consists of repeating units either monosaccharide or disaccharides joined together by glycosidic linkages. They mainly occur in nature as functional and structural components of cells (e.g., glycoproteins and glycolipids), or merely as non-informational storage forms of energy (e.g., glycogen). The structure of repeating unit of the marine bacterial polysaccharide is shown in Fig. 3 (Senni *et al.*, 2011). Commonly found monomer units in polysaccharides are glucose, fructose, mannose, galactose and aminouronic acids. The various polysaccharides differ from one another not only in the composition of the constituent monosaccharide but also in the molecular weight, degree of branching, glycosidic linkage pattern and type of configurations involved in the respective monosaccharide units.

Commercially available polysaccharides used in food and nonfood industries as stabilizers, thickness and gelling agents, crystallization inhibitors and encapsulating agents etc., are also called hydrocolloids or gums. Additionally, polysaccharides exhibited various pharmaceutical fields, papermaking, biological activities such as antitumor, anti-inflammatory, anti-bacterial and immunologic activity as well as anti-mutagenic activity. Table 2 (Stiger-Pouvreau *et al.*, 2016; Verbeke *et al.*, 2003; Alphons *et al.*, 2009; Choudhary and Pawar, 2014) shows the source, sugar presents and linkages in some naturally occurring polysaccharides. Polymer derived from 100% renewable agricultural resources can be depolymerized by acids and heat, specific enzymes and high pH. In order to reduce the amount of non-biodegradable plastic waste (a serious environmental problem), polysaccharides serves as an alternate for its biodegradability. One of the drawbacks is, it has poor mechanical properties due to its hydrophilic behavior which causes earlier rupture. At the molecular level, the polysaccharides structuring are encountered with either ordered or disordered conformations. Polysaccharides may adapt secondary structures because of sugar residues linked through glycosidic linkages. More than 20 several monosaccharide units are combined through glycosidic linkages form polysaccharides. Based on the number of different monomer units in the structure, polysaccharides can be divided into homo polysaccharides (has single sugar unit on the backbone) and hetero polysaccharides (more than one sugar unit). Storage polysaccharides such as starch and glycogen, and structural polysaccharides such as cellulose and chitin, were mainly found in the nature.

Properties of Polysaccharides

Polysaccharides contain a large number of hydroxyl groups, oxygen atoms, and other groups that may interact with water molecules mainly through hydrogen bonding. These interactions control the mobility of water in food systems, affect ice crystal formation and growth, and thus may exert a particular influence on the textural and functional properties of foods. According to solubility (Murray, 2009), some polysaccharides insoluble in water or organic solvents, (e.g., cellulose), some are soluble in hot

Fig. 3 Structure of marine bacterial polysaccharides.

Table 2 Classification of Naturally occurring Polysaccharides

Polysaccharides	Source	Sugar present and linkages
I Sea weeds		
1. Agar	Red algae (Gelidium species)	D-Galactose β -(1 $\rightarrow$ 4), 3,6-anhydro – L-galactose α -(1 $\rightarrow$ 3), + sulfate acid ester groups
2. Algin	Brown algae (Macrocystis pyrifera)	D-Mannuronic acid β -(1 $\rightarrow$ 4), L-guluronic acid β -(1 $\rightarrow$ 4), Na salt
3. Carrageenan	Red algae (Chondrus crispus, Gigartina stellata)	3-linked β -D-galactose 4-sulfate and 4-linked 3,6-anhydro- α -D-galactose.
4. Fucoidan	Brown algae (Fucus sp., Laminaria sp.)	L-Fucose + sulfate acid ester groups
II Plant exudates		
1. Gum Arabic	Acacia sp.	L-Arabinose, D-Galactose, L-rhamnose, D-glucuronic acid
2. Ghatti	Anogeissus latifolia	L-Arabinose, D-xylose, D-galactose, D-mannose, D-glucuronic acid
3. Karaya	Sterculia urens	D-Galactose, D-xylose, D-glucuronic acid
4. Tragacanth	Asteragalus sp.	D-Galactose, L-rhamnose, D-galacturonic acid
III Plant extracts		
1. Pectin	Cell walls and intracellular spaces of all plants (commercial source, citrus waste)	D-Galacturonic acid α -(1 $\rightarrow$ 4) partially esterified, L-arabinose, α -(1 $\rightarrow$ 5) and α -(1 $\rightarrow$ 3) branches, D- galactose β -(1 $\rightarrow$ 4)
2. Larch	Western larch	D-Galactose, L-arabinose
IV Plant seeds		
1. Corn-hull	Corn seed coat	D-Xylose, L-arabinose, galactose and glucuronic acid
2. Guar	Camposia tera gonolobus endosperm	D-Mannose β -(1 $\rightarrow$ 4), D-galactose α -(1 $\rightarrow$ 6) branches
3. Locust bean	Carob tree (Ceratonia siliqua) Endosperm	D-Mannose β -(1 $\rightarrow$ 4), D-galactose α -(1 $\rightarrow$ 6) branches
4. Quince seed	Cydonia vulgaris	L-Arabinose, D-xylose, hexuronic acid, monoethyl, hexuronic acid
5. Psyllium seed	Plantago sp.	D-Xylose, L-arabinose, D-galacturonic acid, L-rhamnose, D-galactose
6. Flax seed	Linum usitatissimum	D-Galacturonic acid, D-xylose, L-rhamnose, L-arabinose, L-galactose, D-glucose
7. Tamarind	Tamarindus Indica	D-Glucose, D-Galactose, D-xylose
8. Wheat gum	Wheat	D-Xylose β -(1 $\rightarrow$ 4), L-arabinose branches
1. Cellulose Derivatives	Plant cell walls, wood pulp and cotton	D-Glucose β -(1 $\rightarrow$ 4)
2. Starch Amylose Amylopectin	Cereal grains and tubers	D-Glucose α -(1 $\rightarrow$ 4), D-glucose α -(1 $\rightarrow$ 4), α -(1 $\rightarrow$ 6), at branch points
3. Dextran	Bacterial action on sucrose	D-Glucose α -(1 $\rightarrow$ 6) and α -(1 $\rightarrow$ 3)
4. Chitin	Exoskeleton of animals of the phylum Arthropoda	N-Acetyl, D-glucosamine β -(1 $\rightarrow$ 4)

water (e.g., starch) and some are soluble in cold water (e.g., pullulan or gum arabic). Highly branched polysaccharides are easily dissolved in water due to the irregularity of molecular structure which prevents the formation of a closely packed structure and allows many polymers to hydrate. On the other hand, linear polysaccharides with regularity in molecular structure are insoluble in water. Natural polysaccharides are less soluble than the charged ones (polyelectrolytes) (Wang and Cui, 2005).

The functional properties of various natural polysaccharides like flow, solubility, water holding capacity (WHC), oil holding capacity (OHC), angle of repose, and bulk and true density were studied and the results were summarized by Sarkar *et al.* (2018). Babchi gum has 1% outstanding flow ability and Piyaar gum (Buchanania lanzan) has the highest bulk density of 1.25 g mL⁻¹ and true density of 1.66 g mL⁻¹. The solubility index is higher for Khair gum (83.65%), the WHC for Psyllium gum (1024.66) and tamarind gum showed the highest OHC (214.66 g oil 100 g⁻¹ gum⁻¹). Guar gum showed increase in the angle of repose (39.80°). One of the direct methods to determine the molecular weight of polysaccharide is osmotic pressure (π). It is calculated by using the formula $\pi = \Delta h \rho g$ (where Δh is the difference in heights of the liquid in the column, ρ is the density of the solution and g is the acceleration due to gravity) through static membrane osmometer. This method is less sensitive to high molecular weight polysaccharides. Also, for neutral and charged polysaccharides, the measurement can be made in water and 0.1M-1M NaCl solutions respectively. The weight-average molecular weight (M_w) of native kondagogu gum and deacetylated gum were determined to be 8.5×10^6 and 2.5×10^7 g mol⁻¹, respectively, by 'Static Light Scattering' experiments.

Viscometry is the most widely used and another straight forward method to determine the molecular weight of polysaccharides. Intrinsic viscosity can be measured with the help of relative viscosity (η) and the concentration (c) of the polymer taken. Using Mark-Houwink equation, $\eta = kM_v^\alpha$, the viscosity is measured. The parameter k and α are primarily dependent on the geometry of the inter-residue linkages within the polymer chain. α values for various gums were given by Vinod *et al.* (2008) and it can be used to distinguish, if a polymer has a compact (close to 0.5 and has lower intrinsic viscosity) extended (close to 0.8 or higher intrinsic viscosity) conformation. On the other hand polysaccharide with expanded coil conformation gives high values of k values and low k values for compact coil conformation. Conformation of the polysaccharides gives the idea of 3D orientation of a specific polysaccharide in space, and the orientation of the glycosidic groups presents the projections of sugar moieties in the chain. The traditional method (Ubbelohde Viscometer) is used to find the relative viscosity of polysaccharides $\eta_{rel} = \frac{t}{t_s}$ where t is the time period for solution and t_s is for solvent. The intrinsic viscosities $[\eta]$ of native and deacetylated gum kondagogu were observed to be

$32.68 \pm 0.23 \text{ dL g}^{-1}$ and $59.34 \pm 1.38 \text{ dL g}^{-1}$, respectively in 1.0 M aqueous NaCl. The zero shear specific viscosity, for polysaccharides, was found to be close to 10 mPa·s at critical concentration.

There are various techniques to analyze the thermal property of polysaccharides such as dynamic mechanical analysis (DMA), differential thermal analysis (DTA), thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC). But the distinguished and common technique is used to characterize the polysaccharide gel is DSC. The cooling curve of 3.2% and 1% of gellan gum exhibited a sharp exothermic peak at $\sim 40^\circ\text{C}$ (T_s) while the heating curve has a sharp endothermic peak at temperature (t_m) slightly greater than T_s (Miyoshi *et al.*, 1996). Gum tragacanth and hydroxyethyl cellulose exhibited the highest (258 kJ mol^{-1}) and the lowest (121 kJ mol^{-1}) activation energy of thermal decomposition, respectively. Most of the DSC traces indicated a major intense exothermic transition (around 300°C) followed by weaker exotherm(s). TGA showed two phase of weight loss, one is due to the desorption of moisture as hydrogen bound water to the saccharide structure and the second phase is due to the polysaccharide decomposition. Furthermore, the initial decomposition temperature (IDT) and integral procedural decomposition temperature (IPDT) was calculated for the seed polysaccharides such as gum Arabic (IDT 274.6°C and IPDT 375°C), gum tragacanth (IDT 252.3°C and IPDT 366°C), xanthan gum (IDT 266.4°C and IPDT 383°C), sodium alginate (IDT 225.1°C and IPDT 381°C), Chitosan (IDT 293.0°C and IPDT 417°C), *D. melonoxylon* (IDT 221.21°C and IPDT 563.3°C), *B. lanzan* (IPDT 170.4°C and IPDT 598.1°C) and *M. zapota* (IPDT 178.6°C and IPDT 600.6°C) respectively. The presence of certain percentage of carbon, nitrogen, sulfur and hydrogen are identified through the elemental analysis (Bothara and Singh, 2012). Similarly gum kondagogu has revealed the contents of carbon, hydrogen, nitrogen and sulfur to be 34.97, 5.58, 0.229 and 0.128 (w/w %), respectively.

Polysaccharides based films are poor barrier against water vapor permeability coefficient (WVPC) and other polar substance at high relative humidity (RH), whereas at low to intermediate RH, the films has good barrier against O_2 and other non-polar substances. According to starch based films, the water vapor transmission rate (WVTR) is 4–6 times greater than the conventional films made from synthetic polymers (Dole *et al.*, 2004). Arabinoxylan films have low O_2 and CO_2 permeability but high water vapor permeability coefficient (Grondahl *et al.*, 2006).

End-of-Life of Polysaccharides

Polysaccharide based end products show better environmental profiles than their conventional counterparts in terms of non-renewable energy use (NREU) and greenhouse gas (GHG) emissions. Starch, a degradable polymers have lower calorific values than non-degradable LDPE, hence by incineration, less energy could be recovered from thermoplastic starch (TPS). This implies that for the system cradle-to-grave, the inclusion of waste incineration with energy recovery could invert the energy saving benefit for starch polymers. TPS leads to lower GHG emissions than petrochemical LDPE or HDPE. The value of GHG emission saving of TPS was $1.2\text{--}3.7 \text{ kg CO}_2 \text{ eq kg}^{-1}$, $\pm 15\%$ (Patel *et al.*, 2003) and $1.1\text{--}2.1 \text{ kg CO}_2 \text{ eq kg}^{-1}$ was reported by James and Grant (2005). Due to its better biodegradability and biocompatibility, the polysaccharides were not accumulated in the environment. However, when it was chemically treated or modified or blended with high melting temperature oil based polymers, the disposability can create issues. The goal for new products is to design in such a way that after their period of service they can be reused, recycled or disposed of, without negative impact on the environment. Options for disposal at the end of the product life cycle require that the materials can be fully degraded by environmental influences such as temperature, UV light, water and microbial attack. Most polysaccharides are known to degrade under conditions where bacterial and enzymatic degradation can occur. Mineralization of polysaccharide derivatives may proceed substantially slower by different composting routes (Persin *et al.*, 2011). Starch were added to polyethylene (PE) to enhance degradation under natural environments resulting the disintegration of 6% starch added PE bags in soil was complete within 3–6 years. 40% starch blends with PE and copolymer of PE and acrylic acid (PEAA) partially disintegrated and lost a substantial amount of starch when exposed to pond and river water. Also, the chemical structures of the PE and PEAA polymers were unchanged. Starch-added products may disintegrate as litter in natural environments, but are probably not effective in reducing accumulation of landfill solid waste after municipal disposal (Hamilton *et al.*, 1995).

Polysaccharides such as cellulose and hemicellulose are a principal biodegradable polymer in MSW and could be degraded under the aerobic conditions found in landfills. It has been estimated (Barlaz *et al.*, 1990) that 41% of municipal refuse is composed of paper and paperboard, 7.9% is food waste, and 17.9% is yard waste. The majority of cellulose and hemicellulose in landfills therefore originate from forest products.

Conclusions

The present article briefly reviewed the works related to polymers from renewable resources. The properties such as solubility, poly disperse index, molecular weight, viscosity, density, DSC, barrier properties (O_2 , CO_2 , WVPC), tensile strength, modulus etc., and EOL like disposal, recycling, incineration, composting and landfills etc. were discussed. Polymers (PLA, PHA and polysaccharides) from renewable resources have received greater attention because of its biodegradability, the environmental compatibility. The production of PLA has number of advantages compared to other polymers. PLA produces an excellent ecofriendly polymer during polymerization. PLA biodegradation is highly dependent on temperature and moisture since these two factors promote hydrolysis of the polymer chains, and in turn accelerate biodegradation. Recycling entrepreneurs may explore means of recovering and recycling PLA in a cost effective fashion. PHAs are natural, biodegradable, non-toxic, hydrophobic, optically active, biocompatible,

and synthesis from renewable resources. Due to this behavior, it has a wide range of application. These properties and better environmental performance create a bright future for PHA and expected to be a good candidate to substitute PP and PE, but also PET in certain applications. PHAs are fully biodegradable in both aerobic and anaerobic. Commercially available polysaccharides used in food and nonfood industries. Polysaccharide based end products show better environmental profiles than their conventional counterparts in terms of non-renewable energy use (NREU) and greenhouse gas (GHG) emissions. Hence, it can be concluded that the PFRR have better physical properties that make it as a suitable material to replace conventional materials as reinforcement in the existing polymer industry. As a major source of indigenous raw material in polymer industry not only provides a biodegradable resource, but also provides a chance for economic development in rural areas.

Properties of Coconut Fiber

S Sengupta and G Basu, ICAR-National Institute of Research on Jute & Allied Fibre Technology, Kolkata, India

© 2016 Elsevier Inc. All rights reserved.

Introduction

Coconut trees ([Fig. 1](#)) are grown in the coastal regions in the wet tropical areas of India, Sri Lanka, Philippines, Indonesia, Malaysia, Fiji Islands, Vietnam, Hawaii Islands, Papua New Guinea, and Solomon Islands mainly. It is grown for the high oil content of the endosperm (copra), which is widely used in both food and non-food industries (e.g., margarine and soaps). The coconut trees are having a life span of about 80 years. Coconut is the seed of a species of palm, *Cocos nucifera*, and its fiber is the fibrous husk of the coconut shell ([Fig. 2](#)). The most suitable soil for the coconut is rich alluvial or loam having adequate soil moisture either through well-distributed rainfall, percolation of soil moisture, and drainage system alongside the backwater. The coconut also yields well in lateral loamy or black clayey soil. It generally grows in an atmosphere of saline moisture, light wind with heavy and well-distributed rainfall and high-humidity and moderate climate ([John, 1970](#)). Large-production areas, in particular, are found along in these countries millions of people make a living from the coconut palm and its many products. Total world productivity has increased substantially from 35 MT around 1980 to almost 50 MT today ([John, 1970](#); [FAO, 2004, 2008](#)). These palms flower on a monthly

Fig. 1 Coconut trees on the shore of backwater lagoon.

Fig. 2 Cross section of matured coconut fruit.

basis and the fruit take 1 year to ripen after 3–5 years of plantation. A palm tree may have fruit in every stage of maturity. A mature tree can produce 50–100 coconuts per year. Generally, a coconut weighs 1.0–1.2 kg per nut of which, weight of husk is around 300–400 gms (NRDC, 2009). This husk contains about 30% of textile quality fiber and rest small fibers (Pits) and small fragments (Pith). Green coconuts, harvested after about 6–12 months on the palm, contain pliable white fibers to dehydrated rigid brown fibers. These fibers are mainly used for making ropes/twines, carpets, furnishings, floor matting, wall decorative, fancy bags, etc.

The quality of coconut fiber depends upon several factors, viz., agro-ecological conditions (rainfall, humidity, soil, etc.), variety of seedlings and most importantly on stage of harvesting and process employed for extracting the fiber. A good-quality fiber can be obtained from the green coconut husk when they are in naturally hydrated condition. The fiber at this stage found to be whiter, flexible, softer, and easy for chemical processing. However, as copra is the prime product of coconut, hence the dehusking is generally done when the coconut reached to its full maturity after 9 months and fibers are matured, dehydrated, and yellow to brown in color. Raw fibers (Fig. 3) are retted conventionally in backwater for about 6–12 months (Manilal *et al.*, 2010) to make it softer. Recently, chemical retting has been proposed by Basu *et al.* (2015) using a combination of Na_2S , Na_2CO_3 , and NaOH ; which can improve fiber property after 2 h of treatment (Fig. 4).

Fine Structure of Fiber

Scanning Electron Microscopy

The observation of the scanning electron micrographs of the raw fiber surface (Fig. 5(a)) reveals cracks, voids, and parallel ridges, which are further connected with intermediate nodes perpendicular to fiber length forming more or less rectangular indentation. The non-uniformity seen in this fiber is probably caused by heterogeneous distribution of impurities, fat and waxy substances, and

Fig. 3 Raw fiber.

Fig. 4 Retted fiber.

Fig. 6 Cross section of a coconut fiber. Reproduced from Mishra, L., Basu, G., 2013. Coconut fibre – Journey from food to fibre. In: Satapathy, K.K., Ganguly, P.K. (Eds.), *Diversification of Jute and Allied Fibres: Some recent Developments*. Kolkata: ICAR-National Institute of Research on Jute and Allied Fibre Technology, pp. 335–348.

globular protrusions. The surface morphology of backwater retted fiber (**Fig. 5(b)**) has more irregularities and impurities than the raw fiber, which might be due to formation of an additional salt coating through its backwater retting followed by air drying without washing. Comparing to raw and backwater retted coconut fibers, treated fibers appeared to be clean, with a smoother surface and it is possible to observe a reduction on fats and waxes (**Fig. 5(c)**). Alkali treatment removes the surface adhered impurities leading to formation of rough surface with pits which were not revealed on the surface of raw and backwater retted fibers.

Cross-Sectional View

The cross-section of fiber (**Fig. 6**) is circular having central lumen. Presence of numerous voids around central lumen indicates its multi-fibrillar structure. The scanning electron micrograph shows the micro-fibrills by longitudinal parallel ridges. Uneven fiber surface with prominent cracks and micro-pores are detectable. Irregular wax-like deposition on the fiber surface masking the cracks,

and micro-pores in places, is visible in the micrograph. In this context, it may be noted that the fats and wax contents was found to be 1.03% as estimated by solvent extracted method.

Physical and Mechanical Properties of Fiber

Mechanical and physical properties of coconut fiber are shown in Table 1 where it is being compared with two allied popular lignocellulosic fibers viz., jute and sisal.

Length and diameter

Coconut fiber is notably thicker than sisal and jute. The diameter and length of coconut fiber, both are highly variable having range values 100–795 μm (average being 183 μm) and 44–305 mm (average being 320 mm), respectively. Linear density (59.2 tex) of coconut fiber is much higher as compared to jute (3.8 tex) and sisal (29.67 tex). However, apparent density and true density are 1.17 and 1.40 g cm^{-3} respectively comparable to jute and sisal. High linear density along with low length–diameter ratio (750) of coconut fiber indicates its suitability for coarse textile applications.

Mechanical property

Table 3 shows that, breaking tenacity (11.25 cN/tex) and initial modulus (200 cN/tex) of coconut fiber are notably lower than those of other two natural fibers. This may be due to its lower degree of crystallinity (45%) as compared to jute (58.7%) (Samanta *et al.*, 2008) and sisal (71.7%) (Kalia *et al.*, 2011). Coconut fiber showed relatively high extensibility of even up to over 21%, in contrast to the other natural fibers, jute (1.8%) and sisal (2.76%). High extensibility ultimately resulted in high-specific work of rupture (13.4 mJ/tex-m) of coconut fiber as compared to jute (2.8 mJ/tex-m) and sisal (4.41 mJ/tex-m). The extension of coconut fiber indicates spiraled cellulosic macro-molecular arrangement in the fiber having high angle of orientation (Stern and Stout, 1954). The fiber is having much higher degree of flexural rigidity (1473 mN-mm²) as compared to jute and sisal, may be attributed to its high-lignin content, coarseness, and

Table 1 Physical and mechanical properties

Property parameter	Coconut	Jute	Sisal
<i>Physical parameters</i>

Note: Bhattacharya, G.K., Basu, G., Chattopadhyay, S.K., *et al.*, 2009. Coconut Fibre and Its by Products: Present Status and Potentiality. Kolkata: ICAR-National Institute of Research on Jute and Allied Fibre Technology.

nearly circular cross-section. Coconut fiber showed 59.3% instantaneous recovery and in total 81.5% recovery at 2 h on removal of compressive load. High-flexural modulus along with good resiliency indicates its high-shock resistance property.

Frictional property

Coefficient of friction for coconut fiber (0.35 in parallel direction and 0.30 in perpendicular direction) is lower with respect to jute (0.45 in parallel and 0.40 in perpendicular) and sisal (0.56 in parallel and 0.51 in perpendicular). This indicates its lack of inter fiber cohesiveness. This may be attributed, to the much less area of contact between the coconut fiber surfaces due to (1) more circularity in its cross-section as compared to jute and sisal, (2) hardness of fiber surface, (3) irregular fiber contour, and (4) high-flexural rigidity of coconut fibers, ultimately resulting in less welding effect.

Electrical resistance

It shows the maximum resistance of $4 \Omega\text{-kg m}^{-2}$, while sisal and jute show 2.96 and $1.83 \Omega\text{-kg m}^{-2}$, respectively. In semi-crystalline polymers, current flows mainly through the crystalline regions (Pathania and Singh, 2009). Hence coconut fiber, which is a low crystalline fiber, compared to jute and sisal, shows higher resistance. Additionally, presence of lignin up to 45%, which is hydrophobic in nature, inhibits the flow of current through the fiber matrix. High insulation property indicates its potentiality in use of electrical insulating materials.

Microbial decomposition

Accelerated testing for microbial decomposition reveals that coconut fiber retained 60% of its original strength even after 75 days, while, jute and sisal lost their strength within a period of 21 days. High durability of coconut fiber may be attributed to its higher lignin and much lesser hemicellulose and pectin content as compared to jute and sisal (Bhattacharyya and Paul, 1980; Rosa Medeiros *et al.*, 2010).

Moisture

Coconut fiber showed good moisture regain (11.7%) and moderate to high water absorbency (63%). Moisture absorption resulted in moderate swelling of coconut fiber up to 50%. On the contrary, sisal despite having greater amount of cellulose (67–78%) in its macromolecule (Rahman and Khan, 2007), has low absorbency mainly due to its higher degree of crystallinity and wax content (Basu *et al.*, 2011). It was observed that coconut fiber shows an apparent hydrophobic nature with water. This may be attributed to high carbon to carbon (C–C) and carbon-to-hydrogen (C–H) bonds of surface lignin (Mahato *et al.*, 2009), which initially hinder the aqueous treatment.

Distribution of Different Properties of Coconut Fiber

Wei and Gu (2009) analyzed length and fineness characters of coconut fibers (Table 2) from a bunch of randomly taken from a fiber stack. The fiber-length distribution is given below. It is found that longer fibers usually have higher diameters.

Table 3 summarizes the statistical distribution data, viz., extreme values, mean, median, mode, coefficient of variation (CV), skewness, standard error of skewness, kurtosis and standard error of kurtosis, of property parameters of coconut fiber. It is clear from the table that all the physical properties have high variation. Majority of the fibers are lying in the range of 4–12 cm length, 100–200 μm diameter, and 10–20 tex linear density. This is mainly attributed to their natural inheritance. In coconut fiber, this variability is much higher due to poor extraction process and unorganized collection which mixes fibers of different maturity and varieties. To test the normality of all the characteristics, its skewness and kurtosis were evaluated. All the properties were shown to have skewed asymmetric curve. Similarly, kurtosis values, which are not zero, indicate that none of the characteristics follow normal distribution; either it is leptokurtic (positive value) or platykurtic (negative value). The distribution curves are shown in Fig. 1. Since, it is evident that all the characteristics are asymmetric in nature; Kolmogorov–Smirnov (K–S) goodness-of-fit test (Massey, 1951; Miller, 1956) is applied at a significance level $\alpha \geq 0.5$ to ascertain the best-fit curve, where highest K–S probability value represents the best asymmetric curve. Table 4 shows the K–S distribution and K–S probability values of fiber length for different probability density functions. The highest K–S probability value of 0.199 for Weibull function indicates the best-fit function for that property. All other properties of coconut fiber were tested likewise and the best-fit functions of different properties along with its K–S probability value are listed in Table 5.

An extensive work (Sengupta *et al.*, 2014) deals with variation in different physical properties within a lot of coconut fibers randomly selected from mixture of fibers taken from a specified agro-ecological region in India. Natural fibers inherently differ

from each other to a great extent. Information on average values of various property parameters and variability of each property parameters is essential to a processor to identify or to design processing machines to convert the fiber to value-added products. For any industrially processable fiber crop, an evenly distributed property parameter is most desirable to the processor. The results (Table 3) show that all the major property parameters of coconut fiber are highly variable and follows asymmetric distribution curve. It indicates the chance of coming out with highly variable textile products from processing machines in spite of taking all the possible measures to produce regular thread-like materials (twines and cordages) and any finer sheet-like materials. High variability in fiber length (Fig. 7(a)) causes high hairiness protruded from thread surface. It becomes difficult to engineer finer materials if the diameter is highly variable. High variability in diameter and linear density indicates that coconut fiber may be used in making much coarser materials like household ropes and cordages. However, length-wise segregation of fiber would solve the problem to a considerable extent. Considering the asymmetric distribution (Fig. 7(a)), the fibers may be segregated in following three major length-groups, namely (1) long, (2) medium, and (3) short. Figures reveal that number of medium length fiber is substantially higher than short followed by long fibers. The distribution of diameter as well as linear density values also shows nearly similar trend. In this case number of coarse fiber is substantially higher than medium followed by fine fibers. So, the fiber mix may also be sorted by diameter or linear density (Figs. 7(b))

Fig. 7 (a) Length distribution of coconut fiber. (b) Diameter distribution of coconut fiber. (c) Linear density (fineness) distribution of coconut fiber. (d) Strength distribution of coconut fiber. and 7(c)). Due to differences in linear densities, segregation may be done by centrifugation or winnowing the fiber mix. The segregated fibers may be used for producing three different groups of materials. Long and coarse fibers may be used for producing conventional ropes and coarse RESM-S, while medium length and fine fiber may be used for making finer textiles materials with improved property parameters, either elementarily or in blends with other fibers. Short fibers may be used in making flexible or semi-rigid composites and also used as geofibre (Balan, 2004) for soil stabilization.

It may be worth noting that distribution of mechanical property parameters (viz., breaking tenacity and elongation) are much less asymmetric (Figs. 7(d) and 7(e)) as compared to the dimensional property parameters. The coefficient of variation of breaking tenacity (47.3%) and breaking extension (37.5%) is lower than the CV of length (50.9%) and diameter (52.9%). Distribution of specific work of rupture and flexural rigidity has been shown in Figs. 7(f) and 7(g), respectively. Specific flexural rigidity values were highly asymmetric with CV, 94.3% (Fig. 7(h)). The increased coefficient variation, in this case, may be attributed to the combination of the two highly variable physical parameters, flexural rigidity and linear density. The problem has been further aggravated due to variation in diameter along the length of individual fiber.

Diameter Distribution along the Fiber Length

Fig. 8 shows variation in fiber diameter along the fiber length. Sixty fibers were selected randomly and divided into three equal parts as fine, medium, and coarse according to its linear density. Diameter of all the fibers was measured from base to tip in 1 cm interval. The diameter of different fibers gradually increases from base to a mid-point, and then starts decreasing till the tip ends. The diameter of coarse fiber changes from 493 to 263 μm having the highest diameter at 550 μm with the coefficient of variation of 21.2%. The diameter of fine fiber changes from 93 to 91 μm having the highest diameter of 187 μm with the coefficient of variation of 25.6%. This may be one of the major reasons for high coefficient of variation of different fiber properties. Fig. 2 reveals that individual fiber possesses variable diameter along its length tapering off at both the ends.

Inter-Relation between Two Fiber Properties

Among the fiber properties studied, length, diameter, and linear density can be studied easily. A rough estimation of these parameters can be done without any sophisticated instrument. A simple stainless steel scale graduated in 10 divisions of a centimeter and an ordinary magnifying glass may be used to measure length and diameter, whereas a simple weighing balance may be used to get linear density. Therefore, it has been tried to understand the relationship (Table 5 and Figs. 9(a)–9(c)) between these three parameters individually with other fiber properties (Sengupta *et al.*, 2014) so that those properties can be predicted from these three primary parameters. The properties which are poorly correlated and insignificant with fiber length are not shown graphically.

Length is the most important primary parameter to judge fiber quality. This study shows a good correlation of fiber length with diameter (0.759), linear density (0.799), braking load (0.834), and specific work of rupture (0.743), out of which first three are positively correlated, whereas specific work of rupture is negatively correlated, i.e., with increase of length, it decreases. The significance of these relations has also shown by student *t*-test (significance level $\alpha \geq 0.5$) and corresponding *p*-value. Tenacity, breaking extension, flexural rigidity, and specific flexural rigidity are poorly correlated with length and this is supported by the

Fig. 9 (a) Effect of fiber length on diameter. (b) Effect of fiber length on linear density. (c) Effect of fiber length on breaking load. (d) Effect of fiber length on specific work of rupture. (e) Effect of diameter on linear density of fiber. (f) Effect of diameter on breaking load of fiber. (g) Effect of diameter on specific work of rupture of fiber. (h) Effect of diameter on flexural rigidity of fiber. (i) Effect of linear density on breaking load of fibers. (j) Effect of fiber linear density on specific work of rupture. (k) Effect of fiber linear density on flexural rigidity.

t -test and p -values. **Table 5** shows the best-fit equations for each relation. Diameter, linear density, and braking load follow the second order polynomial, whereas specific work of rupture follows exponential curve. **Figs. 9(a)–9(d)** show the effect of fiber length on diameter, linear density, braking load, and specific work of rupture of fibers.

Diameter is another important primary parameter for fiber quality assessment. This study shows a good correlation of fiber diameter with length (0.799), linear density (0.893), braking load (0.785), specific work of rupture (0.826), and flexural rigidity (0.764) out of which first three are positively correlated. The significance of these relations is also shown by student t -test (significance level $\alpha \geq 0.5$) and corresponding p -value. Tenacity, breaking extension, and specific flexural rigidity are poorly correlated with diameter and this is supported by the t -test and p -values. **Table 5** shows the best-fit equations for each relation. Diameter is related with linear density by linear equation and load by second order polynomial, whereas other properties exponentially. **Figs. 9(a)** and **9(e)–9(h)** show the effect of diameter on length, linear density, braking load, specific work of rupture, and flexural rigidity of fibers.

Linear density is an important primary fiber quality for processability point of view. This study shows a good correlation of linear density with length (0.799), braking load (0.804), specific work of rupture (0.934), and flexural rigidity (0.739), out of which length, braking load, and flexural rigidity are positively correlated, i.e., with increase of linear density other parameters increases, whereas

specific work of rupture is negatively correlated, i.e., with increase of linear density it decreases. The significance of these relations is also shown by student *t*-test (significance level $\alpha \geq 0.5$) and corresponding *p*-value. Tenacity, breaking extension, and specific flexural rigidity are poorly correlated with linear density and this is supported by the *t*-test and *p*-values. Table 5 shows the best-fit equations for each relation. Diameter and braking load follow the second order polynomial, whereas others are related exponentially. Figs. 9(b) and 9(i)–9(k) show the effect of linear density on length, braking load, specific work of rupture, and flexural rigidity of fibers.

In all the cases, it is apparent that the relations of easily measurable parameters (length, diameter, and linear density) with breaking tenacity and specific flexural rigidity are very poor due to the combined effect of very high variability of linear density as well as basic parameter, i.e., breaking load or flexural rigidity. High linear density variation may be due to the age of the fibrous elements within or between the nuts. On reaching the maturity level, deposition of biological elements increases in both longitudinal and radial directions of the individual fibrous element as duration increases before harvesting. Furthermore, the diameter as well as linear density also varies along the length of fiber. The breaking extension is always poorly correlated, as it is mainly governed by weak places and structural defects of fibers and not by the basic fiber parameters. That is why the extensibility of fibers is unpredictable by length, diameter, and linear density.

The best-fit equations with significant correction coefficient help to predict major fiber quality parameters (linear density, breaking load, specific work of rupture, and flexural rigidity) by easily measurable parameters (length and diameter). Since, the grading is generally done at growers' field or at the market yard, our aim is to assess the quality characteristics of fiber in shorter period of time adopting minimum number of easily measurable parameters. The predicted values will help to grade the coconut fiber lot in farmers' field by measuring length and diameter using ordinary scale and magnifying glass. By this process the farmer will fetch good economic return from the fiber.

Textile and non-textile products prepared from the fibrous materials depend on fiber property and structural parameters of end product (Goswami *et al.*, 1977). The major dimensional and mechanical property parameters of fibers include length, diameter, linear density, strength, elongation, work of rupture, and flexural rigidity. Longer and finer (lower linear density) fiber produces stronger, regular, and less hairy products. Soft fiber (low flexural rigidity) requires much less energy to twist a fiber bundle to make thread-like material. Soft fiber also yields stronger and softer textile materials. The increase in linear density, caused due to increased deposition of lignocellulosic matters, restricts intermolecular movements during bending, resulting in high rigidity. Toughness (specific work of rupture) depicts the combined effect of fiber strength and elongation, and it indicates end use performance of the product. The stated fiber parameters also decide some other important product functional parameters, i.e., handle, insulation, etc.

Defects in Fibers

Four main defects are identified namely (1) coconut peat, a dust-like matter of small particle size (10.64%); (2) mid-joint, a sticky bark-like matter at the middle of fiber (6.03%), (3) branched fiber, branching out from the main fibrous element (2.35%), and (4) insect bite (2.31%). On physical verification, it is found that the coco-peat would be removed from the fibers during their mechanical processing, such as opening, cleaning, and drawing. Similarly, the mid-joints would also be opened up during the same processing machines. So, coco-peat and mid-joints may be considered as minor defects. Though, weight loss to an extent of 10% (or more) may cause monetary loss to the fiber processing units. Some branched fiber and insect bitten may be remained in the fibers even after initial mechanical processing and this would not be suitable for mechanical conversion to finer or value-added end products. So, branched fiber and insect bite may be considered as the major defect. Different defects are shown in Figs. 10(a)–10(d) (Sengupta *et al.*, 2014).

Defects in fiber are one of the major parameters of fiber quality in terms of its processability, generation of waste and quality of the output of the machine. Minor defects are generally eliminated during processing of fiber and most of them are generally dropped down during processing in the machines and do not affect the end product quality. However, minor defects have some economic importance due to the waste generated from fiber lot. Among the major defects, branched fiber may cause generation of hairiness on the yarn surface. Insect bitten fiber may affect strength and appearance properties of the intermediate or of the end product.

Chemical Properties of Raw Coconut Fibers

Chemical Composition

The chemical composition of coconut is given in Table 6, which shows that brown coconut fiber contain relatively low amounts of cellulose but have high-lignin content. The exceptionally high-lignin content implies that the available dyeing and bleaching techniques for textile fibers cannot simply transferred to coconut fibers/products.

Treatment with Water

Treatment with water (Table 7) at boil and steaming for 2 h causes weight loss of 2.6 and 7.2% respectively in raw coconut fiber. Water treatment at boil leaches out part of the water soluble matters. However, under steaming, water insoluble matter including pectin, low-molecular-weight hemicellulose fraction apparently gets leached out contributing to additional weight loss. The flexural rigidity value of 1273 cN mm² of the raw coconut fiber has lowered to 1235 and 1177 cN mm² on boiling and steaming the fiber for 2 h respectively (Basu *et al.*, 2015).

Pectin	0.5
Ash	1.6
Fats and waxes	1.1

Treatment with Sulphuric Acid

The treatment (Table 7) using H_2SO_4 (40% and above) at ambient temperature, results in surface carbonization with gradual solubilization (complete or partial) of the fiber. However, for concentration of 30% and below for H_2SO_4 , the fibers resist the treatment for 1 h without any surface carbonization. The action of HCl is milder than H_2SO_4 , which shows no surface carbonization under the

treatment conditions. However, both the treatments made the fiber brittle during storage even after alkali neutralization, probably due to hydrolysis of cellulose polymers by the acids (breakage of the β -1,4-glycosidic bonds of cellulose) (Huang and Fu, 2013).

Treatment with Oxidizing Agent

The treatment (Table 7) of strong oxidizing agent NaIO₄ with coconut fiber (alkaline pH) results in more reduction in tensile properties than in flexural rigidity. This may be due to possible chain scission of 1,2-diols linkages of cellulose to form aldehydes and ketones (Hong *et al.*, 2009). Oxidizing agent, H₂O₂ (alkaline pH) is also not found to be sufficiently suitable to reduce the fiber flexural rigidity, though there is no adverse effect observed on the tensile properties of the fiber.

The treatment with Na₂S (Treatment No. 6), showed high weight loss (17.6%) and larger reduction in flexural rigidity, diameter, linear density and thereby increased the length to diameter ratio, improving the mechanical properties of coconut fiber. The reaction of Na₂S can be explained on the basis of its hydrolysis to convert into NaHS and finally to NaOH. The high alkalinity at elevated temperature of the treatment partially hydrolyzes the components of coconut fiber. Apart from this, NaHS reacts with lignin to introduce -SNa group which increases its acidity and solubility in alkaline medium. The Na₂S being a reducing agent retards the rate of hydrolysis and oxidation of cellulose (Tomlinson, 1950) causing lower damage to the fiber structure. Treatment of coconut fiber was also carried out using alkaline aqueous solution of NaOH and Na₂CO₃ separately. The individual treatment of NaOH and Na₂CO₃ has moderate reducing effect on fiber flexural rigidity.

The combination of Na₂S with NaOH reduces the flexural rigidity and breaking tenacity more than that of combination of Na₂S with Na₂CO₃. However, the binary treatments (Treatment No. 8 and 9), show lesser effect on fiber softening properties than the individual treatment of Na₂S (Treatment No. 6).

The ternary combination of Na_2S , Na_2CO_3 , and NaOH treatment (Treatment No.10 of Table 7) is found to be most effective in all respect. The combination of 40% Na_2S , 15% Na_2CO_3 , and 20% NaOH causes highest weight loss (about 28%) without affecting the tensile property. The treatment also reduced flexural rigidity, linear density, and diameter significantly resulting in enhancement of length to diameter ratio (Table 1). It is assumed that the combination of alkalis (NaOH , Na_2CO_3) might enhance the effect of Na_2S . Alkalis swell the structure of the fiber causing easy penetration of Na_2S for disruption of internal fiber structure. Further, in any natural fibers, the addition of alkali reduces the surface negative ion concentration by the excessive supply of Na^+ ion, which facilitates better reaction of the chemical with the fiber. Alkalis also tend to reduce the surface tension of the natural fibers and helps in saponification and emulsification of fat and wax (present on fiber surface of most natural fibers), which otherwise hinders the water based treatments. Besides pure cellulosic components, hemicelluloses and alkali soluble lignin part are solubilised or precipitated out by alkalis. The presence of Na_2CO_3 provides some action of detergency to the treatment solution and thus helps in holding the dirt and other insoluble impurities in the suspension from depositing on the fiber surface.

Chemical Properties of Retted Coconut Fibers

The change in major constituents of raw coconut fibers, due to backwater and newly developed chemical retting is given in Table 8. The chemically retted fiber shows considerably higher α -cellulose (54.2%) than both backwater retted (39.6%) and raw (38.4%) coconut fiber. The increase in cellulosic content is also evident in FTIR and XRD of chemically retted fibers. Chemical treatment resulted in reduction of lignin content of raw coconut fiber from 31.8 to 26.3%. The reduction of lignin content possibly decreases the flexural rigidity of the fiber up to a certain extent. The analysis also reveals notable reduction in other constituents of the fiber like hemicelluloses, pectin, fats, and waxes, and ash content due to chemical treatment. The removal of constituents other than cellulose (viz., lignin, hemicelluloses, pectin, fats, and waxes), which are not contributing toward the tensile parameters probably cause much better mechanical properties in terms of higher breaking tenacity, and work of rupture in chemically retted fiber. The trend of removal of constituents like, hemicelluloses, pectin, and fat and wax matters is also evident in backwater retting, but the extent of removal is trivial.

Infrared Spectrum Analysis

Fig. 11 shows the FTIR spectra of the (a) raw (b) conventionally backwater retted, and (c) accelerated chemically retted coconut fiber. It can be seen from the three spectra that, no considerable change occurs either in position or in appearance/disappearance of the peaks. However, there was a change in intensity of some of the peaks, such as 1250 , 1332 , and 1513 cm^{-1} observed. The broad and intense peak at $\sim 3340\text{ cm}^{-1}$ suggesting OH stretching vibrations from cellulose and lignin intensified in chemical retted fibers. The characteristic bands of hemicelluloses and lignin observed around 1741 cm^{-1} due to the conjugated $>\text{C}=\text{O}$ stretching of ester and aldehyde reduced more in chemically treated coconut fiber than the conventionally backwater retted fiber. No change is observed in β -glucosidic linkage peak of celluloses at 897 cm^{-1} in backwater retted and raw fiber. However the same peak intensifies slightly in case of chemically retted fiber. The C–O–C stretching absorption peak of cellulose at 1038 cm^{-1} remain similar in the three fibers (Samal *et al.*, 1995; Samanta *et al.*, 2008). This proves backwater retting and chemical retting do not affect the celluloses part of coconut fibers. However, the absorption peaks at 1250 cm^{-1} correspond to CO– stretching of esters, ethers and phenols groups attributed to the presence of waxes in the epidermal tissue (Brigida *et al.*, 2010) and at 1513 cm^{-1} correspond to lignin aromatic ring stretching (Mahato *et al.*, 2009), both drastically reduced in the chemically retted fiber due to the removal of wax and lignin respectively during chemical retting/softening of fiber.

Crystalline Structure Analysis

Fig. 12 shows the radial X-ray diffractogram of the three coconut fiber samples. Crystallinity Index (C.I.) of the chemically treated coconut fiber (54%) is much higher than the C.I. of the raw fiber (37%) and retted fiber (42%) as estimated by amorphous subtraction method. The diffractogram peaks (mainly peak 002) for the chemically retted fiber intensified considerably and got sharpened than the others indicating an enhancement of crystalline perfection due to removal of non-crystalline material like lignin, hemicellulose, pectin, etc., by the chemical treatment. Similar results were also reported by different authors (Varma *et al.*, 1984; Sreenivasan *et al.*, 1995) while discussing the effects of alkali treatments on coconut fibers.

Table 8 Chemical composition of coconut fiber (weight % on oven dry basis)

Components	Raw/unretted	Backwater retted	Chemically retted
α -Cellulose	38.44 ± 0.7	39.64 ± 0.21	54.16 ± 0.13
Lignin	31.84 ± 0.48	31.95 ± 0.02	26.29 ± 0.05
Hemicelluloses	24.54 ± 0.15	22.73 ± 0.9	14.04 ± 0.01
Pectin	0.5 ± 0.01	0.37 ± 0.03	0.00
Ash	1.41 ± 0.03	1.46 ± 0.06	0.76 ± 0.03
Fats and waxes	1.12 ± 0.001	1.09 ± 0.07	0.75 ± 0.01

Thermal Analysis

The results of thermogravimetric analyses for raw, backwater retted and chemically retted coconut fibers are shown in [Fig. 13](#) and summarized in [Table 9](#). It can be seen that, decomposition of fibers are characterized by the temperature range. The initial decomposition of fiber takes place for evaporation of water and volatile substances (low-molecular-weight waxes and fats) occurs

between room temperature and 150°C. The second weight loss corresponds to hemicelluloses degradation, starts at about 190°C. Weight loss occurs between 290 and 360°C mainly corresponds to cellulose degradation. Lignin degradation starts at about 280°C and continues even above 500 °C (Rosa *et al.*, 2009).

The chemical treatment have a considerable change on the thermal degradation behavior of coconut fibers as compared to raw and backwater retted fibers, which possess resembling profile of weight loss. The initial weight loss attributed to evaporation of water and volatile substances was found to be lowest (6.8%) for chemically retted fibers due to removal of some easily hydrolyzed substances (waxes and fats) during chemical treatment. The comparatively higher weight loss (8.5%) for evaporation of water observed in backwater retted fibers than raw (7.4%) fiber possibly due to the extra moisture adsorbed by the salty layer present on fiber surface (as constituent analysis reports similar content of fats and waxes). Chemically treated fiber showed markedly lower weight loss of 21.8 and 21.5% under the transition temperature range of 150–330 and 590–700°C respectively, as compared to raw and backwater retted fiber. The comparatively lower weight loss occurred in chemically treated fiber for the temperature range, is indicating the reduction in hemicelluloses and overall lignin content than the other two fibers. Chemically retted fiber showed notably higher weight loss (49.1%) in the temperature range of 330–590 °C as compared to weight loss observed for raw (39.2%) and backwater retted (39.1%) fiber. The higher weight loss for the said region is indicative of the degradation of notably higher amount of cellulosic material present in chemically retted fiber. Chemically retted fibers are left with much less residue of 0.7% as compared to residue left in case of raw (2.8%) and backwater retted (2.6%) fiber.

Differential Scanning Calorimetry

Fig. 14 shows DSC thermogram of coconut fiber. The relatively low temperature wide endothermic peak at 84.17°C is attributed to the evaporation of absorbed moisture and volatile substances (low-molecular-weight waxes and fats) of the fiber (Samanta *et al.*, 2008). The second weight loss corresponds to hemicelluloses degradation at temperatures 241.01°C (long). Degradation at 284.11°C (small) may be due to pectin (Ali *et al.*, 2009) and hemicellulose (Samanta *et al.*, 2008) jointly. Among the two major constituents of coconut fiber, an endothermic peak at 364°C is representative of cellulose degradation while, lignin, being the most resistant, shows an exotherm peak at 390.7°C and its degradation still continued till 497°C.

Quality Specifications

Retted Coir Fiber/White Fiber

Retted coir fiber, also called white fiber, is extracted from green natural coconut husks after retting in flowing, circulating or changed water for a period of minimum 3 months. However, if the fiber is made out of pre-crushed husks the retting period could be reduced suitably. The fiber shall be free from moisture and impurities. Grading has been shown in **Table 10**.

Brown Fiber

Brown fiber is mechanically extracted from the dry husks of matured and ripe coconut after soaking these husks in water. The fiber shall be free from moisture and impurities.

Length of fiber: The mechanically extracted coir fiber shall be grouped based on the length

Long fibers above 20 cm

Fig. 14 DSC curve for coconut fiber. Reproduced from Basu, G., Mishra, L., Jose, S., Samanta, A.K., 2015. Accelerated retting cum softening of coconut fibre. *Industrial Crops and Products* 77, 66–73.

Table 10 Grading of retted/white coconut fibers

Grade	Color	Maximum impurities percent by weight
1	Natural bright	2.0
2	Natural light brown and/or light gray	3.0
3	Natural brown and/or gray	5.0
4	Natural dark brown and/or dark gray	7.0

Length of Fiber: The length of fibers shall be designated as follows:

'Long' over 15 cm.

'Medium' over 10 and up to 15 cm.

'Short' over 5 and up to 10 cm.

'Bit' up to and including 5 cm.

Medium fibers above 15 and up to 20 cm

Short fibers above 5 and up to 15 cm

Grading of bristle, mattress, and decorticated coconut fibers have been shown in **Tables 11–13**, respectively.

Conclusions

- Property-based advantages of coconut fibers:
 - Resistant to fungi and rot.
 - Provides excellent insulation against temperature.
 - Not easily combustible.
 - Flame-retardant.
 - Resistant to moisture and dampness.
 - Tough and durable.
 - Resilient; springs back to shape even after constant use.
 - Totally static free.
 - Easy to clean.
- Coconut fibers are multi-cellular, lignocellulosic, hard, a very coarse, and rigid variety of natural fruit fiber.
- The quality of coconut fiber, depends upon agro-ecological conditions (rainfall, humidity, soil, etc.), variety of seedlings and most importantly on stage of harvesting and process employed for extracting the fiber.
- A good-quality fiber can be obtained from the green coconut husk when they are in naturally hydrated condition. The fiber at this stage found to be whiter, flexible, softer, and easy for chemical processing.
- Scanning electron micrographs of the raw fiber surface reveals cracks, voids, and parallel ridges, which are further connected with intermediate nodes perpendicular to fiber length, forming more or less rectangular indentation. The cross-section of fiber is circular having central lumen.
- Distribution of all the physical properties such as length, diameter, linear density, breaking tenacity, breaking extension, specific work of rupture, flexural rigidity, and specific flexural rigidity of the raw coconut fibers are of asymmetric nature with high coefficient of variation.
- Diameter of a fiber varies along its length with tapering shape at the both ends.
- Length, diameter, and linear density – three dimensional properties are positively correlated among themselves. All these dimensional parameters are positively correlated with breaking load and negatively correlated with specific work of rupture. Flexural rigidity is positively correlated with diameter and linear density.

9. The major defects of coconut fibers are branched fiber, short and weak fiber, whereas, minor defects are coconut pect and mid-joint.
10. Softening treatment of raw coconut fiber with combination of Na_2S , Na_2CO_3 , and NaOH decreases the flexural rigidity value of raw fiber by 75% without any deterioration of desirable properties viz., strength and elongation.

Recycling of Polylactide

Circular Economy and Valorization of Bioplastics

Due to their high potential of replacement of petroleum-based polymers, the design, use, and disposal routes of bio-based polymers must be carefully strategized to ensure appropriate service conditions and adequate valorization and/or elimination means after their service-life. The balance between the long-term properties and the end-of-life of bio-based polymers is key to set up a design for sustainability (Badia *et al.*, 2017).

Poly (lactic acid) is the polymer resulting from the polycondensation reaction of its monomer, lactic acid. In contrast, the ring-opening polymerization of the cyclic lactide dimer brings up polylactide, which usually results in a polymer with higher molar mass than that of poly (lactic acid). Both are usually termed as PLA in literature and care must be taken to understand its origin previously to its transformation. PLA is an aliphatic polyester and biocompatible thermoplastic, currently considered a promising material with an outstanding development prospect and highlighted as a green eco-friendly material. A review on the properties, origin, applications, and market of PLA is reported by Madhavan Nampoothiri *et al.* (2010). The carbon source for microbial production of lactic acid can be either sugar in pure form such as glucose, sucrose, lactose, etc. or sugar-containing materials such as molasses, whey, sugar cane, and cassava bagasse, or starchy materials from potato, tapioca, or wheat, among others. PLA-based materials are essentially referenced on three different markets: Biomedical, agricultural, and packaging, in the last case mainly for food-contact applications. Manufactured products are blow-molded bottles, injection-molded cups, spoons and forks, thermoformed cups and trays, paper coatings, fibers for textile industry or sutures, films and various molded articles. These applications have a short life and most of the time the goods are discarded leaving their properties intact. One might think that there is a lot of invested time, intellectual effort, and economical resources to create high-tech packages with outstanding properties just to be used and discarded within a few short minutes.

A smart combination of the routes of production, valorization, and disposal might therefore lead to reduce the environmental impact and gear bio-based polymers towards added-value applications.

There are several routes to valorize plastics: (1) material valorization, which considers the obtaining of material from another material, by means of reusing, mechanical recycling or chemical recycling, which is also termed as feedstock recycling; (2) energy valorization, which is aimed at obtaining energy from thermal treatments such as pyrolysis or gasification; (3) biological valorization, which comprises the natural reincorporation of plastics into the carbon cycle, by means of biotic agents such as microorganisms or enzymes. The initial trends of research on bioplastics were focused on their biodegradability, and therefore their end-of-life was designed to be treated in biological valorization facilities such as composters. However, from a circular economy perspective (Spierling *et al.*, 2019), it is advisable to explore the possibilities of potentiating the recovery of plastics towards downgraded, similar, or upgraded applications, by means of material valorization routes, previous to final biological or energy valorizations. The key is to enlarge the path of bioplastics along the cradle-to-cradle journey, and avoid the cradle-to-grave shortcuts.

Among the aforementioned valorization routes, mechanical recycling represents one of the most cost-effective methodologies, since they are economically affordable, the technology is ready, and the know-how is well-established along the transformation pathway. This fact offers discarded bioplastics a new chance to perform at good level of conditions. Therefore, a revision of the most relevant works on the mechanical recycling of PLA is performed in this article. The influence of degradation is evaluated in terms of structural and morphological changes, in close connection with the performance of recycled PLA on its processability, thermal and mechanical properties, and mass transfer capabilities. PLA-based blends and PLA-based nanocomposites are also considered, since they are close to real applications in market.

Mechanical Recycling of PLA

Simulation of Mechanical Recycling

Mechanical recycling is a type of material valorization that uses thermo-mechanical means to produce a new product from another used product. This new product is usually affected by degrading conditions during the whole life cycle of the material, from production to discarding, in addition to the effects of environmental solicitations during their use. Therefore, a new production cycle will affect on their performance and thus usually leads to downgraded applications. In the near future, PLA will probably compete with the commodities' market, and therefore the society must start wondering how to manage the inherent new source of bioplastics waste, since nowadays there are not specific routes for its recovery and valorization at industrial scale. This issue has brought attention to scientists to perform simulations of mechanical recycling and subsequently understand the impact of these processes on its structure and correlated performance.

Fig. 1 Scheme of common experimental approaches to the simulation of mechanical recycling of PLA.

The common experimental approaches to simulate the mechanical recycling of PLA are shown in **Fig. 1**. It usually considers a prestage of drying, due to the high hygroscopicity of PLA, which may lead to hydrolytic reactions during subsequent processing at relatively high temperatures. It is followed by processing, by means of extrusion or mixing and ulterior shaping by injection or compression molding. At lab conditions, it is usually driven to a grinding process, to granulate the material to feed the process again.

It is important to remark that the results in literature concerning recycled PLA have to be taken with care, since it might not be representative of the same recycling route. For instance, during the processing stage, some materials are just taken from the extruded fraction to the subsequent grinding. In these studies, injection or compression molding are used for shaping the probes for mechanical or viscoelastic tests but, in essence, they account for another processing cycle in its lifetime, which is not usually considered in terms of reprocessing cycles. In contrast, in other studies, the grinding is performed after the injected or compressed cycles, and therefore the reprocessing cycle considers both processes in the cycle. Therefore, the comparability of data is somehow compromised. Nevertheless, the trends of the evolution of properties gathered in this article permit to understand in broad terms the influence of recycling on the performance of PLA.

As the reader might wonder, reprocessing and recycling do not essentially represent the same concept, though in literature there is a risk to confuse them. Reprocessing does not take into account the stages of use and sorting, and therefore this simulation is relevant to understand the reuse of leftover flakes in the industry. This is the case of most of the studies found in literature. In contrast, studies that account for the use or sorting of PLA are hard to find. At lab conditions, the use has been simulated by thermo-oxidative aging, usually maintaining the PLA probes in contact with air at high temperature, close to the glass transition temperature. However, no relevant studies have been found simulating recycling of PLA with other plastics in semireal conditions, where the influence of contamination of other fractions could be analyzed.

Under these conditions, the most relevant studies to date that approach the reprocessing of PLA have been gathered in this article, and summarized in **Table 1**. The numbers of reprocessing cycles and the type of main processing stage have been considered, along with the most relevant analytical techniques and specific indicators of quality of the key aspects of PLA, for example, structure, processability, mechanical properties, and mass transfer, which are tackled in the following subsections.

Degradation Mechanisms of PLA Induced by Mechanical Recycling

Thermo-mechanical degradation induced by mechanical recycling of PLA considers the impact of degradation agents such as temperature, oxygen, humidity, mechanical stresses, or light, individually or in combination. Even if technical measures are taken to prevent the contact of PLA with the environment at high temperatures, oxidation, and hydrolysis end up in chain scission reactions; while transesterifications modify the molar mass distributions of the polymers and therefore affect to their morphological properties in terms of amorphous-to-crystalline ratio, chirality, or steric rearrangements. The temperature of many PLA processing routes should not exceed 230°C to avoid thermal degradation via nonradical reactions, which would lead to a significant decrease in molar mass that has an important effect on the performance of PLA.

A particular analysis of the macromolecular species that take place during mechanical recycling of PLA was carried out by *Badía et al. (2011)*. The postulated mechanistic routes, as obtained from MALDI-TOF-MS analysis, along with the evolution of oligomeric species encountered after up to five injection-grinding cycles is shown in **Fig. 2**. The main reactions are hydrolysis (route I), which provoke the formation of hydroxyl and carboxyl linear oligomers with shorter chain length. In addition, esterification and intra- and intertransesterifications (routes II, III, and IV, respectively) occur by backbiting, that is, from the end of the chain, and at the middle of the chain, which leads to the formation of cyclic oligomers and linear species with shorter length, modifying the molar mass distribution. The most remarkable changes were those occurring for linear $H-[LA_L]_n-O-CH_3$ species, which presented a noticeable increase, being the most predominant species after three processing cycles, and achieving a proportion of up to 40% for the fourth recycle.

Structural and Morphological Changes Induced by Mechanical Recycling on PLA

The impact of mechanical recycling on the structure and morphology of PLA will directly determine its final behavior in terms of processability, performance, and durability. Therefore the application of specific techniques to establish proper indicators of degradation is a fundamental step in the design context, as highlighted in **Table 1**.

Fig. 2 Degradation pathways (up) and evolution of oligomers (down) as a result of the application of 5 successive thermo-mechanical cycles. Legends: square: $[LA]_n$; circle: $CH_3-O-[LA]_n-H$; up-triangle: $HO-[LA]_n-H$; down-triangle: $CH_3-O-[LA]_n-CH_3$; diamond: $CH_3-CO-O-[LA]_n-CH_3$, where LA stands for lactic acid repeating unit, L stands for linear and C for cycling oligomeric species. Reproduced from Badía, J.D., Strömberg, E., Amparo, R.G., Karlsson, S., 2011. Assessing the MALDI-TOF MS sample preparation procedure to analyze the influence of thermo-oxidative ageing and thermo-mechanical degradation on poly (Lactide). *European Polymer Journal* 47 (7), 1416–1428. doi:10.1016/j.eurpolymj.2011.05.001.

In this sense, among other techniques, size exclusion chromatography (SEC) permits to determine the molar mass distributions, Fourier-transform infrared spectroscopy (FT-IR) permits following the relative intensity of absorbance of specific functional groups, mass spectrometry (MS) and nuclear magnetic resonance offer the identification of macromolecular distribution of species in the polymer, differential scanning calorimetry (DSC) offers information about the relative amorphous-to-crystalline ratio, and X-ray diffraction (XRD) points out the degree of crystallinity.

To picture the impact of thermo-mechanical degradation on the structure and morphology of PLA, three analyses by means of SEC, FT-IR, and DSC have been selected in Fig. 3.

Reproduced from Badia, J.D., Strömberg, E., Karlsson, S., Amparo, R.G., 2012d. Material valorization of amorphous polylactide. Influence of thermo-mechanical degradation on the morphology, segmental dynamics, thermal and mechanical performance. *Polymer Degradation and Stability* 97 (4), 670–678. doi:10.1016/j.polymdegradstab.2011.12.019.

Badia and Ribes-Greus (2016) reviewed the trends of molar mass evolution of different studies and found a general reduction of the molar mass in number M_n and the viscous molar mass M_v , regardless the molar mass of the virgin PLA, the type of processing or the number of reprocessing cycles, which meant that the PLA backbone suffered from scissions induced by mechanical recycling (Fig. 3(a)).

The most relevant functional group affected by degradation, observed by FT-IR, as shown by Beltrán *et al.* (2018) for PLA, reprocessed PLA and reprocessed PLA with a washing step, is that of the increase of the band related to the stretching vibration of C=O bonds, around 1750 cm^{-1} , which permits tracking degradation by the apparition of new carbonyl-linked species (Fig. 3(b)).

Concerning the amorphous-to-crystalline ratio, the impact will be different depending on the D-isomers of PLA, which induce its intrinsic semicrystalline or amorphous nature. As an example, the DSC traces of the second calorimetric scan, that is, after

erasing the thermal history and applying a controlled annealing ramp, are shown in Fig. 3(c), for PLA reprocessed up to five successive times. In this study, Bruster *et al.* (2016) analyzed a PLA that remained completely amorphous regardless the number of reprocessing cycles. In fact, the melting events at temperatures near 150°C correspond to the fusion of the crystallites formed during the DSC experiment at the so-called cold-crystallization, around 120°C. The assignation of the melting to a real crystalline fraction is, however, one of the main mistakes in literature and therefore the analyses must be taken with care and counterchecked, in case of doubts, with techniques such as XRD.

Nevertheless, it is still possible to establish patterns of degradation by means of indicators taken from DSC, as shown by Badia *et al.* (2012d) from the deconvolutions of the melting event and the proposal of monitoring of T_M^I and A_M^I , that is, the partial melting temperature peak and the partial area of the melting curve, respectively. As can be seen in Fig. 3(c), the shape of the endotherms showed a change from a monomodal to a bimodal distribution, which was attributed to a superimposed melting–crystallization–melting process, dependent on the kinetics of the DSC temperature program. A deconvolution process by means of Gaussian or Lorentzian curves would be helpful to discriminate between low-T and high-T pseudocrystalline populations. As pointed out in the study by Badia *et al.* (2012d), the melting peaks were progressively detached until the second reprocessing step, where the position of the endotherms, characterized by its peak temperature, held unmoved. The evolution of A_M^I decreased progressively reaching almost equal proportions as that of A_M^{II} , as shown in Fig. 3(d). The effect of the thermo-mechanical degradation could be ascribed to the variation of the first area A_M^I , which would be indicative of the promoted tendency of crystals to melt, and thus for molten shorter chains to recrystallize. Both overall decreases of $\sim 5^\circ\text{C}$ in T_M^I and $\sim 47\%$ in A_M^I suggested the presence of weaker cold-crystallized domains along the injection cycles, corresponding to the crystallization of scissored macromolecular chains.

Processability of Reprocessed PLA

The influence of mechanical recycling on the structure in terms of diminution of molar mass or modification of its molar mass distribution will affect the further possibilities of PLA to be reprocessed under similar and standardized technological conditions. It is, in fact, one of the key pillars to ensure a well-established industry of PLA worldwide. In this sense, the thermal stability and the flowing rates of the polymer shall be known and controlled. In this framework, as highlighted in Table 1, among other techniques, DSC and thermogravimetric analysis (TGA) permit to find out the thermal properties in inert or oxidative conditions and therefore determine the thermal ranges of operation and security (Badia and Ribes-Greus, 2016). Glass transition temperature, melting temperatures and enthalpies, onset temperature of decomposition, and mass-loss are the common indicators. Concerning flowability, rheometry (RH) and simpler but effective, viscometry (VISC), and melt-flow index (MFI) assessment are usually considered to assess viscosity or melt-flow rate.

To illustrate the effect of reprocessing on the thermal and thermo-oxidative stability of PLA, along with the impact on the flowability, three analyses by means of TGA, MFI, and RH have been brought to Fig. 4.

Fig. 4(a) shows the thermogravimetric (TG) curves for both virgin and fifth reprocessed polylactides analyzed under inert and oxidative atmospheres (VPLA, RPLA5, VPLA-O₂, and RPLA5-O₂, respectively) at the heating rate $\beta = 5^\circ\text{C min}^{-1}$ (Badia *et al.*, 2012a,c). The region for the induction of thermal and thermo-oxidative decompositions is zoomed in the upper-right region. The recyclates showed similar trends like those revealed by virgin PLA, with no relevant impact on the onset of decomposition. Since the results of thermogravimetry might be dependent on the technique and heating rate, a further analysis in terms of the temperature decomposition behavior (TDB) model and the zero-decomposition temperature (ZDT), which would prevent the results from having kinetic bias, can be found in literature (Badia *et al.*, 2012a,c).

Zenkiewicz *et al.* (2009) performed the measurement of MFI for PLA subjected to 10 successive extrusion–grinding cycles, as shown in Fig. 4(b). The simplicity of this technique allows the plastic industry to perform fast quality control checks and detect unexpected deviations from the desired specifications of thermoplastics. The chain scission induced by thermo-mechanical degradation provokes a reduction of molar mass, which turns evident in terms of increase of the MFI. Therefore, the higher the number of reprocessing steps was applied, the larger the MFI was, and therefore a closer inspection on the rheological behavior at different shear rates is advisable.

Scaffaro *et al.* performed rotational RH to PLA upgraded by an elastomeric impact modifier, and analyzed the evolution of viscosity as a function of frequency. RH permits identifying the flowing behavior at low, medium, and high shear rates and therefore adjust the technological processing parameters to give a new life to the downgraded PLA after recycling. In general, the decrease of the molecular weight was related to a decrease in the viscosity (Scaffaro *et al.*, 2011).

Influence of Recycling on the Mechanical Performance of PLA

Mechanical properties are, along with mass transfer barrier properties, the main issues raised by plastic producers when they face the challenge of using recycled material in their formulations. The capability of plastics to withstand the mechanical solicitations in service has to be therefore ensured in a routinely based manner. Literature frequently refers to mechanical properties of recyclates as better as or worse than those of the virgin polymer. This description of course discusses the resistance properties, but there are other mechanical properties that have to be taken into account such as flexibility, stiffness, toughness, or viscoelasticity, among others. Therefore, more specific descriptions must be detailed when reporting mechanical properties of polymers.

The most used techniques are tensile testing and flexural testing for resistance and flexibility, Charpy impact test to measure toughness, indentation to determine stiffness, or dynamical-mechanical-thermal analysis to understand viscoelasticity. The most

relevant indicators are summarized in Table 1. To explain the effects of reprocessing on the mechanical properties of PLA, three studies have been highlighted in Fig. 5.

A general decrease in the resistance properties was registered by Żenkiewicz *et al.* (2009) in terms of tensile stress and stress at break, as a function of 10 successive extrusion–grinding cycles, as shown in Fig. 5(a). Consequently, the structural changes observed at the macromolecular level have an impact on the endurance of the newly formed crystallites.

Concerning flexibility, Pillin *et al.* (2008) reported the evolution of the ductility, in terms of elongation at break, of PLA reprocessed up to seven cycles, as shown in Fig. 5(b). The steep decrease during the initial reprocessing cycles showed that one of the main problems of recycling is the loss of ductility, which in turn corresponds with an increase of brittleness that reduces its applicability in similar markets.

The influence of thermo-mechanical degradation induced by successive reprocessing in the viscoelastic behavior of PLA was reported by Badia *et al.* (2012d), as shown in Fig. 5(c). The viscoelastic spectra showed different relaxation zones. At temperatures

reaching the glass–rubber relaxation around 55°C, all materials showed a drop in the storage modulus of nearly 99% of the initial value that after a rubbery plateau increased until 5%–8% of the modulus. This behavior may be due to the formation of crystalline phases in the rubber state, regardless the reprocessing cycle or frequency analyzed. Regarding the evolution of the initial storage moduli along the reprocessing cycles, an initial increase up to the second recycle was shown, and afterwards the values decreased to nearly equal values for RPLA-3,4,5. The origin of these results can be understood in terms of cooperative movements within the amorphous phase throughout the glass–rubber relaxation and thus a deeper inspection into the influence of reprocessing into the glass-forming behavior of PLA was performed. A closer inspection on the segmental dynamics and macromolecular cooperativeness of relaxations can be found in literature (Badia *et al.*, 2012d).

Influence of Recycling on the Barrier Properties of PLA

One of the key properties of the polymers in the field of food packaging is their permeability against different gases, such as oxygen, water vapor, nitrogen, or carbon dioxide, among others, in terms of diffusion rate or permeability coefficients. Therefore, the control of the mass transfer behavior of the recyclates represents one of the main focuses of optimization routes in the design of products from recycled fractions.

A relevant report by Żenkiewicz *et al.* (2009) showed that the water vapor and oxygen transmission rates increased by 39% and 18.3%, respectively, in a PLA subjected to 10 reprocessing steps, as shown in Fig. 6.

Impact of Mechanical Recycling of PLA to Subsequent Valorization Routes

Recycled PLA is a source of material that should not be wasted without further valorization. Indeed, there are particular studies that address the possibilities to consider recycled PLA as a new input for material valorization, in the form of blends with virgin PLA

Fig. 6 Effects of reprocessing on permeability of polylactide films: (a) water vapor transmission rates (P_v), (b) oxygen transmission rates (P_o). (Hopmann *et al.*, 2015; Gil-Castell *et al.*, 2018b), a source for energy valorization, both considering pyrolysis or controlled combustion (Badia *et al.*, 2012a,c; Gil-Castell *et al.*, 2018b), or biodegradation by composting (Sikorska *et al.*, 2012). A selection of results of these studies in these fields has been included in Fig. 7, and described in the subsections hereby.

Material Valorization of Mechanically Recycled PLA

The combination of reprocessed and virgin polylactide is considered as a good alternative not only to reduce the material cost at the industrial level, but also as a contribution to further plastic waste management solutions. The incorporation of recycled PLA into virgin/recycled PLA blends (V/R-PLA) has to take into account the structural-to-performance approach presented in the present article for the evaluation of materials. In this sense, the first analysis must be focused on the structural effect, and take into account that, necessarily, at least one more processing step is needed to obtain V/R-PLA blends, which inherently affects the molar mass distribution of polymers. For example, Hopmann *et al.* (2015) evaluated the incorporation of different quotas of recycled PLA on the performance of blends for packaging applications. The reduction of the molar mass of the blend was marginal regardless of the quota of recycled PLA that was present in the formulation up to 50%, for two types of PLA, amorphous and semicrystalline. These researchers also evaluated the impact on the processability by means of the assessment of the viscosity, which suffered from degradation in a higher extent than the molar mass. The study reports that, by using recycled PLA, the viscosity dropped with increasing recycling quota. Due to the low difference of the absolute recycled PLA content, the difference in the range of a recycling quota of 10%–50% was low. Up to a recycling quota of 50%, the average viscosity decreased a 15% for amorphous or a 13% for semicrystalline recycled PLA. Further on, by recycling 100% recycled PLA, the average viscosity drop accounted for 28% for amorphous and 24% for semicrystalline recycled PLA, respectively.

Another study by Gil-Castell *et al.* (2018b) reported the performance of blends prepared from virgin polylactide and polylactide mechanically reprocessed up to two cycles (V/R-PLA), at quotas of 20%, 40%, and 60%, which was assessed in terms of thermo-oxidative stability, morphology, and viscoelasticity. V/R-PLA blends showed appropriate thermo-oxidative stability. The amorphous nature of polylactide was maintained after blending, without relevant modification of the glass transition temperature. Higher rigidity was found for all compounded blends regardless of the composition of recycled PLA, reaching similar values between ~2800 and ~3000 MPa, representing a ~33% of increase with respect to virgin PLA. The viscoelastic properties showed an increment of the

mechanical blend effectiveness (MBE), as shown in Fig. 7(a). This increment was similar regardless of the type of reprocessed PLA incorporated in the blend. The increase of the MBE was more relevant for higher contents of reprocessed PLA in the blend. These results suggested the feasibility of V/R-PLA blends to be used under similar mechanical conditions to those of virgin PLA goods.

Energy Valorization of Mechanically Recycled PLA

Valorization by energy recovery through technological means such as pyrolysis or controlled combustion implies burning waste to produce energy in the form of heat, steam, and electricity. This is only considered a very sensible way of waste treatment when material recovery processes fail due to economical constraints. Plastic materials possess a very high calorific value when burned, especially considering that they are derived from crude oil. Producing water and carbon dioxide upon combustion makes them similar to other petroleum-based fuels.

Badia *et al.* (2012a,c) assessed the impact of five mechanical reprocessing steps on the energy valorization of PLA under inert and oxidative conditions by TGA. The study of the evolved gases, the changes in thermal stability, and the kinetics of decomposition pictured the behavior of recyclates under both thermolytic processes. PLAs, as well as their successive five recyclates, described a mass loss driven by one decomposition stage in inert conditions and two in oxidizing conditions. A first step is ascribed to the pyrolysis of the backbone. A second mass-loss step under O₂ was related to the decomposition of the remaining char (~2%), regardless of the number of reprocessing cycles.

The kinetic model that mathematically described the thermal and thermo-oxidative decompositions of PLA and their recyclates was of the type Avrami–Erofev A_n ; nucleation and growth, which gave importance to the formation of gas bubbles in the melt, as shown in Fig. 7(b). From the second to the third reprocessing cycle, a change in tendency was shown by thermal stability and thermal activation parameters for PLA recyclates. Focusing on each process, under argon the recyclates needed more energy and temperatures to decompose than virgin materials, whereas under oxygen the decomposition of all recyclates was overcome at lower apparent activation energy E_a than that of virgin materials. Thus controlled combustion could be an option to valorize recycled PLA energetically.

Concerning the energy valorization of V/R-PLA blends, it was shown by Gil-Castell *et al.* that the energetic demand for the thermo-oxidative decomposition of V/R-PLA blends was lower and varied in a narrower margin than that of virgin or reprocessed PLA. In particular, the apparent activation energy E_{a_x} increased from ~80–110 kJ mol⁻¹ at low conversions to ~150–200 kJ mol⁻¹ at the end of decomposition. Blending provoked similar E_{a_x} values to reprocessed PLA at low conversion degrees whereas showed lower activation energy at high conversion degrees. In general, V/R-PLA blends showed E_{a_x} values lower than those given by virgin PLA. Therefore, from a cost-effective point of view, considering the energetic demand of each material, the combustion of V/R-PLA blends would result in an advantageous energetic process, thus highlighting the feasibility of the energetic demand for the valorization process (Gil-Castell *et al.*, 2018b).

Biological Valorization of Mechanically Recycled PLA

Biological valorization is the natural route to treat wastes of biodegradable bioplastics, focusing on the reincorporation of the material into the carbon cycle without environmental impact, as raised up by the circular economy philosophy. Within this strategic expression of the eco-effective industrial approach, cradle-to-cradle design defines a framework for designing products and industrial processes that turn materials into nutrients in the carbon cycle.

PLA is not easily biodegraded at service conditions, but is highly liable to composting conditions due to the temperatures close to the glass transition of PLA (Gil-Castell *et al.*, 2018a). Reprocessed PLA is more susceptible to hydrolysis at high temperatures (Badia *et al.*, 2012b). PLA degrades rapidly in the composting atmosphere of high humidity and temperature but at lower temperatures and/or lower humidity, the storage stability of PLA products is considered to be acceptable. In this sense, it would advisable that reprocessed PLA would not introduce complications in the management of their wastes and could be therefore treated without further modification of the already defined technological parameters of composting.

Sikorska *et al.* (2012) evaluated the degradation profiles of multireprocessed PLA under industrial composting conditions at the static composting open-air pile. The progress of the degradation process was monitored by surface changes and measurements of sample weight loss and changes in the molecular weight of the PLA samples. As shown in Fig. 7(c), the repetitions number of the processing experiments of PLLA in the extruder only slightly affected the disintegration progress of the PLLA samples, without further effect on the biodegradation rates. Nevertheless, there were not produced new constraints to disintegration and therefore the same valorization routes could be applied for virgin and recycled PLAs.

Mechanical Recycling of PLA-Based Blends and Nanocomposites

To prevent the problem of degradation during reprocessing, different strategies can be followed, from the incorporation of specific additives to minimize degradation, to the incorporation of PLA into blends or the reinforcement of PLA by different nanoloads to give nanocomposites (Badia and Ribes-Greus, 2016).

Concerning additives, there are antioxidants and stabilizers such as dianthraquinone, benzoyl peroxide, dycumil peroxide, tropolone, or quinine, among others that act by neutralizing the radicals and preventing degradation in properties such as

resistance, flowability, or UV protection. In addition, the use of chain extenders based on acrylates or phosphites can prevent PLA from degradation during reprocessing (Badia and Ribes-Greus, 2016).

Regarding blends and nanocomposites based on a PLA matrix, some selected studies have been brought to this section, to picture the advantages and drawbacks of each option. Blends of PLA with polyethylene glycol (PEG), thermoplastic starch (TPS), or poly (3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) have been considered (Sirin *et al.*, 2014; Zembouai *et al.*, 2015; Brüster *et al.*, 2016). For the case of nanocomposites, PLAs reinforced by nanoceramic fillers of clay and chalk, lignocellulosic loads of cellulose nanocrystals (CNCs) and wood flour, or carbon-based graphene nanoplatelets (GnP) (Bhattacharjee and Bajwa, 2017; Fazelinejad *et al.*, 2017; Beltrán *et al.*, 2018; Botta *et al.*, 2018; Dhar *et al.*, 2018) are summarized hereinafter.

Mechanical Recycling of PLA-Based Blends

The use of plasticizers to improve the processability and versatility of performance of PLA is of relevant importance. The mechanism of degradation of PLA-based blends during mechanical recycling was investigated by Brüster *et al.* Multiple reprocessing of a plasticized PLA grade obtained by grafting poly(ethylene glycol) methyl ether acrylate (acryl-PEG) within PLA via reactive extrusion was reported (Brüster *et al.*, 2016). As can be seen in the DSC curves in Fig. 8(a), in contrast to the behavior shown in Fig. 3(c), the presence of acryl-PEG hindered cold-crystallization and offered nucleation sites to increase the crystallinity of the blends. In addition, the mechanical resistance properties strongly worsened from the first processing to the third processing and the material became brittle since it markedly lost tensile ductility and its toughness dropped. As a result, the authors concluded that at the actual state, plasticized PLA by reactive extrusion could not be recycled and reused for the same application.

Blends of PLA and TPS have been also subjected to four extrusion and injection processing cycles by Sirin *et al.* (2014). The thermal stability of the blends decreased as the TPS content increased in the blend. Multiple recycling negatively influenced the thermal transition temperatures of the blends, such as T_g and T_m . Owing to the presence of starch particles in the PLA matrix, heterogeneous nucleation occurred in the PLA phase for the blends, and was followed by the reduction of the cold-crystallization of the blends. As a general conclusion, PLA/TPS blends were more sensitive to recycling in comparison with neat PLA.

Zembouai *et al.* (2015) reported the mechanical recycling of blends based on PLA and PHBV 50/50 wt% by subjecting them to six extrusion and injection cycles. It was concluded that the thermo-mechanical PHBV degradation was significantly reduced in the presence of PLA. Consequently, the mechanical properties of PLA and PHBV/PLA blends were less affected after six cycles contrary to neat PHBV, which exhibited a reduction.

Mechanical Recycling of PLA-Based Nanocomposites

It might be generally expected that PLA-based reinforced composites have less recyclability than their neat thermoplastic matrix, because composites are more sensitive to thermo-mechanical degradation. Thus, recycling is usually guaranteed up to several reprocessing cycles until the mechanical properties are conserved and then they are discarded for biological or energy valorization. Several nanofillers can be considered for the preparation of nanocomposites, such as nanoparticles or nanofibers, from synthetic or natural origin, which will affect their assimilability once their service lives are covered and they are discarded. Some examples have been chosen to picture the main effects of reprocessing on nanocomposites for PLA reinforced with ceramic nanoparticles such from clay (Beltrán *et al.*, 2018) or chalk (Fazelinejad *et al.*, 2017), lignocellulosic compounds like CNCs (Dhar *et al.*, 2018) or wood fiber (Bhattacharjee and Bajwa, 2017), or carbon nanosources such as GnP (Botta *et al.*, 2018).

Beltran *et al.* (2018) studied the influence of recycling on PLA/nanoclay composites by means of an extrusion–compression–grinding process that also included accelerated thermal and photochemical aging steps to simulate the degradation experienced by postconsumer plastics during their service-life. Mechanical recycling caused an improvement in the dispersion of the clay

Fig. 8 Examples of effects of recycling on PLA-based blends and nanocomposites. (a) DSC second heating trace of PLA plasticized with poly(ethylene glycol) subjected to 1, 3, and 5 processing cycles. Reproduced from Brüster, B., Addiego, F., Hassouna, F., *et al.*, 2016. Thermo-mechanical degradation of plasticized poly(lactide) after multiple reprocessing to simulate recycling: Multi-scale analysis and underlying mechanisms. *Polymer Degradation and Stability* 131, 132–144. doi:10.1016/j.polymdegradstab.2016.07.017; (b) Influence of the addition of graphene nanoplatelets (GnP) into PLA on the rheological viscosity after 1, 3, and 5 recycling cycles. Reproduced from Botta, L., Scaffaro, R., Sutera, F., Mistretta, M.C., 2018. Reprocessing of PLA/graphene nanoplatelets nanocomposites. *Polymers* 10 (1). doi:10.3390/polym10010018.

nanoparticles into PLA. It was concluded that the effect of accelerated aging and the mechanical recycling processes on the properties of the nanocomposite were not extremely aggressive. In the case of permeability to gases such as O₂, N₂, or CO₂, it clearly decreased as a result of the mechanical recycling, being less relevant for N₂ and O₂. This behavior was explained considering two interesting opposite effects. On the one hand, the polymer degradation during service and the recycling process, which might favor the permeation because of the increase of the free volume related to a molar mass decrease in glassy polymers. On the other hand, the tortuosity brought by the nanoplatelets, which may prevent the mass transfer and therefore limit the permeability of these gases. Nonetheless, in general terms, the recycled nanocomposites had similar or even better properties in some cases than those of the virgin material, so the use of recycled nanocomposites in demanding applications could be guaranteed, and even in the same applications as the virgin material is achievable.

Another study performed with a load of 30% of chalk into a PLA matrix, conducted by Fazelinejad *et al.* (2017) revealed promising conclusions for the recycling industry. It was concluded that PLA/chalk nanocomposites could be recycled up to six times without being subjected to any significant change in the mechanical and thermal properties, analogous to that of the virgin PLA matrix.

When it comes to the recycling of PLA reinforced by lignocellulosic loads, Dhar *et al.* (2018) studied the mechanical recycling of PLA filled by CNCs. Like most users, CNCs are usually added to the PLA matrix to improve structural and gas barrier properties, and also to enhance biodegradability, in contrast to other fillers. However, due to the hydrophilic nature of CNCs and the presence of sulfate groups, it results in agglomeration and provokes the initiation of hydrolytic degradation of the PLA backbone. The use of dicumyl peroxide at low content (1 wt%) as crosslinking agent was reported to maintain and even increase by 6%–10% the molar mass after three recycling processes. In addition, the reinforcing effect of CNCs and the action of DCP to ease extrudability was also prevalent by the recycled PLA/CNC films due to the presence of high fractions of grafted PLA/CNC gel-like structures, which showed improved tensile strength by ~16%–30%, increased the maximum degradation temperature by ~7–12°C, and enhanced the viscosity of polymer nanocomposite melts by ~10 times and the storage modulus by ~50 times after the third recycling step.

Bhattacharjee and Bajwa (2017) focused on the effect of six successive mechanical recycling steps on PLA reinforced by oak wood flour, coupled by maleic acid. The results showed how composites experienced a decrease in tensile modulus, flexural modulus, and storage modulus with successive recycling, while they exhibited an increase in failure strain, coefficient of thermal expansion, and melt flow index. With consecutive reprocessing, composite thermal stability increased, while polymer crystallinity decreased.

Regarding the use of nanocarbon sources on PLA, Botta *et al.* (2018) reported the effects of five extrusion recycling cycles on PLA reinforced by GnP. They consist in stacked nanosheets of graphene with relevant electrical, thermal, or resistance properties, and good biocompatibility and innocuous environmental effect after discarding, due to its carbon–carbon nature. A relevant effect of the addition of GnP is pictured in Fig. 8(b), which compares the rheological behavior of PLA and PLA/GnP after 1, 3, and 5 extrusion cycles. The viscosity of nanocomposites was slightly higher than that of neat PLA. Even more, the viscosity of PLA/GnP after five reprocessing cycles was still similar to that of neat PLA. It was attributed to the interaction of the disperse filler with the matrix, which restricted polymer chain displacements. At low frequencies, the behavior of PLA/GnP was more similar to non-Newtonian than unfilled PLA. At high frequencies, the drop was less pronounced if compared with that of unfilled PLA, which was attributed to the positive effect of GnP to reduce degradation phenomena. In addition, improved dispersion of GnP due to reprocessing further increased the nucleating role of the nanofiller. Also the stiffness of the PLA filled with GnP increased as a function of the reprocessing cycles for all the extrusion steps and did not modify the ductility to a high extent.

Conclusions: The Challenge of Mechanical Recycling of PLA

The future presence of PLA in the fractions of polymer waste encourages technologists to ascertain its valorization at the best quality conditions. Mechanical recycling of PLA represents one of the most cost-effective methodologies, but the recycled materials are usually directed to downgraded applications, due to the inherent thermo-mechanical degradation affecting its mechanical, thermal, and rheological performance. During mechanical recycling, PLA is subjected to the influence of degrading agents such as oxygen, light, mechanical stresses, temperature, and water, which, separately or in combination, during its material loop (synthesis–processing–service life–discarding–recovery), results in chemical and physical changes that alter their stabilization mechanisms and long-term properties. In particular, it mainly induces hydrolytic chain scissions and inter/intramolecular transesterifications, affecting the molar mass distribution and subsequently the performance of PLA. A set of opportunities for the field of recycling of PLA was given by Badia and Ribes-Greus, focusing on aspects such as (1) the investment in sorting technologies, to obtain relevant homofractions of polymers; (2) the closer knowledge of the structure-to-performance relationship, with special focus on the influence of the enantiomeric nature of PLA; or (3) the research to potentiate the studies of additives such as stabilizers and chain extenders to lengthen the service life and enlarge the recycling capability of PLA, among others (Badia and Ribes-Greus, 2016). Despite the fact that the focus is already moving from lab scale to pilot scale, the technological challenge will come in the near future when PLA is implemented in the market and suffers from degrading conditions during storage and use at different environments, mixing during discarding, and cross-contamination with other plastics during sorting and valorization. Therefore, larger investments should be considered to bring PLA from an alternative to a reality, within the cradle-to-cradle perspective of the circular economy of bioplastics.

Rice Straw as a Raw Material for Pulp and Paper Production

Wael A Elhelece, Egyptian Nuclear and Radiological Regulatory Authority, Cairo, Egypt

© 2020 Elsevier Inc. All rights reserved.

Introduction

Rice straw is an agricultural byproduct even it could be considered as a waste, rice straw could be utilized as a raw material for pulp and paper production. The chemical composition of rice straw varies from season to season and depends on species. The chemical analysis of an Egyptian rice straw sample is given: Alpha cellulose 41.8%, Pentosans 21.6%, Lignin 13.6%, Ash 18.4% and Silica 16.7% (Elhelece, 2010).

The advantages of rice straw for paper and board production could be summarized as; Rice straw found in abundant amount, rice straw are found in a steady and continuous supply over the years. Also, rice straw is easily collectable, easy of baling and easy of transportation to the factory site. Rice straw is cheap and have no more valuable or profitable use. Rice straw is capable of being stored for at least one year without deterioration. Storage and protection means for storage should be not costly.

It should be noted that rice straw due to its open structure is easily pulpable and does not require hard pulping conditions. Moreover, the price of rice straw is much cheaper than other agricultural residues. Even without recovery of chemicals, production of chemical pulp from rice straw was economically feasible (Raafat *et al.*, 2009).

The disadvantages of rice straw for pulp paper production could be summarized as follows:

High ash content (mainly silicon dioxide) is particularly harmful to cutting tools and to chemical recovery systems in the pulp and paper industry. This difficulty could be overcome, the silica content has been removed simply by an immersion process in a sodium hydroxide solution to obtain desilicated rice straw. However, production of pulp consumes about 500 tones water based on the weight of raw material. The disposal of this great water amount directly into water stream causes environmental pollution. Other alternatives were proposed. The spent liquor instead of being discharged in a body of water can be used, as it is, for different purposes. One of the uses is the direct application of the lignin in the liquor as adhesive in brick industry (El-Kassas and Mourad, 2013).

Also, the strength properties of straw pulp are relatively poor compared to wood pulp and therefore, application to produce brown grades such as sack Kraft, bag Kraft and liner board is generally avoided.

Rice straw must undergo several operations in order to produce paper. These operations are:

- (1) Preparation of the raw material,
- (2) Pulping procedure will be done to separate and clean the fibers,
- (3) Bleaching procedure will be followed after pulping processes,
- (4) Dilution process to form a thin fiber mixture,
- (5) Screening formation of fibers on a thin screened,
- (6) Pressurization to enhance the materials density,
- (7) Drying to eliminate the density of materials,
- (8) Finishing procedure to provide a suitable surface for usage.

Pulping

Rice straw had to be dried and cut into pieces. Lignin molecules and other impurity molecules present in rice straw could be eliminated through mechanical, semi-mechanical and chemical treatments.

In mechanical pulping, the lignin cementing the fibers is destroyed but not removed. The fibers are separated from each other but they still retain the lignin.

In semichemical pulping mild, reduced pulping conditions are used. About 70% of the lignin is dissolved out and the separation of the fibers is not enough. Therefore, the pulp is mechanically treated in refiners in order to liberate more and more fiber. The obtained pulp still contains around 7% lignin based on pulp.

In chemical pulping, more severe pulping conditions are applied. These conditions result in removal of over 95% of the lignin. In the case of easy bleachable pulps, the lignin left in the pulp amounts to not more than 2% based on pulp. Consequently, chemical pulping can be safely termed as "Delignification". These pulps are classified as "soft" pulps when well-cooked and are of high purity and have good tearing strength. When pulps are not well cooked, they are classified as "hard" and are of lower purity and have high bursting strength and high bleach consumption. Chemical pulps do not need further mechanical treatment in fibrators or refiners to complete the liberation of the individual fibers. Sometimes such treatment might be necessary, but only for a short period. For chemical pulping there are two major processes in use. Both processes depolymerize and solubilize the lignin (Evon *et al.*, 2010a).

Semichemical Pulping Process

All processes of semichemical pulping deliver high yield pulp. In semichemical pulping a mild or reduced chemical treatment is applied to the raw material. This treatment is just capable of dissolving lignin partially, and leads to incomplete release of individual fibers. We get rather fiber aggregates. However the remaining lignin in the treated raw material becomes sufficiently soft to be destroyed by a further mechanical treatment. Semichemical pulping is economical because of the high yield it delivers, and the low chemical consumption. In semichemical pulping only 30%–50% of the lignin and 35%–40% of the hemicellulose is removed. On the other hand, in ordinary chemical pulping 90%–95% of the lignin is removed and 60%–68% of the hemicellulose is removed. The yield of semichemical pulp varies between 65% and 85% compared to less than 50% or 40% in the case of chemical pulping. The properties of semichemical pulp are intermediate between whole fibers (e.g., mechanical pulp) and full chemical pulp. Any of the pulping reagents used in chemical pulping can be applied for semichemical pulping but under much reduced conditions of concentration, temperature, pressure and pulping time. However, there are some chemical reagents used specifically for semichemical pulping, namely sodium sulfite alone or in mixture with sodium hydroxide and/or sodium sulfide. The neutral sulfite method uses sodium sulfite and some sodium hydroxide which acts as a buffer to neutralize the organic acids which are formed when the raw material is heated at 120°C and more. When making a bleachable pulp, the yield should not exceed 70% by semichemical pulping. This assures that a sufficient amount of lignin is dissolved out. Thus, the bleaching process can be effective and a degree of brightness of 70% could be achieved. The conditions of semichemical pulping are adjusted according to the type of pulp which has to be produced, the coarse-grade pulp or high-grade pulp. After chemical treatment, the cooked mass is then refined without washing in a disc refiner. For semichemical pulping, batch cooking in rotary digesters can be used. Continuous cooking equipment is preferable. This has the advantage of continuous operations and the great advantage of delivering the cooked raw material quickly to the refiner at high temperature. An example of such equipment is the defibrator chemipulper. A reaction chamber is used which consists of a series of closed, horizontal stainless steel screws. This equipment embodies a combination of continuous digestion and continuous mechanical refining under pressure. In the case of coarse pulps, the most desirable combination of high yield and acceptable strength is obtained in the yield range 70%–80%. The obtained coarse pulp is suitable for making corrugating medium, coarse wrapping paper, liner board, hardboard, insulating board etc.

Pulps for the finer grade of paper (e.g., book, bond, glassine waxing and tissue paper) have to be produced in lower yields. Bleachable grades are made by adjusting cooking conditions to a lignin of about 10% content. This pulp can be bleached in a single hypochlorite stage to give a brightness of 70%–75% without appreciable loss in strength. Even it was possible to obtain pulps at atmospheric pressure, low temperature and low chemicals concentration. Semichemical pulp when used alone in the paper furnish, it produces paper with high bursting strength but with low tear strength, and the paper tend to be too stiff and ratty. When blended with chemical pulp in small ratio, paper acquires good properties (Evon *et al.*, 2010b).

Chemical Pulping

Chemical pulping means cooking rice straw with chemicals on heat. Pulping was done by using classic reagents as soda (with anthraquinone and parabenzoquinone as additives), potassium hydroxide, formic acid and Kraft process. Pulping with NaOH in different concentrations is the easiest method. The heating is done for different time periods until the boiling solution and the straw feels soft or easy to break with your hands and feels sticky, indicating that the straw is ready to be mechanically destroyed. Lignin lost or dissolved in water can be characterized by a brown solution, solution chocolate formed due to lignin and other pollutants dissolved in NaOH, after washing with clean water for several times to keep the straw clean and mechanically destroyed by using a blender. Straw that has been in the blender is dried and ready for use.

The sulfite process makes use of a buffered acid solution of calcium bisulfite or magnesium bisulfite. The sulfur dioxide and bisulfite convert the lignin into soluble lignosulfonic acid and consequently lignosulfonate.

The other process is the alkaline process namely the soda process and it makes use of NaOH solution which reacts with the free –OH groups in the lignin molecules and converts it into sodium ligninate (alcoholate). This is soluble in the cooking liquor i.e., NaOH solution. However a part of NaOH is replaced by Na₂S in order to lower the degradation effect of NaOH on cellulose. Usually Na₂S enhances the delignification due to its reaction with lignin. Accordingly the duration or temperature of pulping can be reduced. This results in stronger pulp and paper and hence the process is called the “Kraft” process referring to the German word “Kraft” means strength. It is called also the sulfate process because sodium sulfate is added in the chemical recovery system where it is reduced to Na₂S (Evon *et al.*, 2012).

The degree of cooking is generally measured by methods which are related to the lignin content of pulp. These are bleachability tests such as permanganate number. Complete purification is not necessary to be achieved in the cooking process, since final purification can be obtained in the bleaching process under milder conditions which are not so degrading on the fiber as pulping.

The acid sulfite process is not suitable for pulping agricultural wastes since these wastes contain a substantial amount of minerals especially silica. These substances cannot be dissolved out in acid medium. On the other hand silica is easily dissolved in alkaline medium. Therefore, for agricultural wastes the alkaline process is recommended. It is also worth mentioning that the Kraft process, which is an alkaline process, accounts for greater than 90% delignification of wood into bleachable grade pulp (Evon *et al.*, 2014).

Variables in Alkaline Pulping

The variables in alkaline pulping are: Composition of cooking liquor i.e., sulfidity etc., concentration of cooking liquor, chemical-to-raw material ratio, temperature and time of cooking. It is important that the liquor penetrates the raw material easily in order to reach the innermost layers of the raw material. The reagent molecules must reach the middle lamella where lignin is located. Thus, the reagent could dissolve the lignin cementing the fibers together, and defibrize the raw material. Fortunately, due to the open supermolecular structure of the cell wall of straws, bagasse and other agricultural wastes, there is no problem facing the penetration of the reagent molecules.

The concentration of the cooking liquor is of prime importance for the rate and extent of delignification. The maximum temperature of cooking (also termed digestion) plays also a great role together with the chemical concentration. These are followed by the time duration of the cooking process. In all cases the alkali is consumed in the early stages of cooking. The mechanism of cooking is not only restricted to delignification but a great part of the carbohydrates fraction especially the hemicellulose is dissolved out. The cellulose also becomes partially degraded as seen by the drop in the molecular weight i.e., degree of polymerization (D.P.) of cellulose. Therefore, the time of pulping or cooking should be adjusted to prohibit substantial cellulose degradation. The cellulose degradation leads to yield loss and decrease in pulp and paper strength. It is well known that D.P. of cellulose is one of the main factors affecting paper strength (Evon *et al.*, 2015).

In contradiction to wood, agricultural wastes are easily penetrable by cooking chemicals and are easily delignifiable. Summing up they are easily pulpable. It is the duty of the chemist in charge of the cooking operation to stop the reaction and blow the digesters at the proper time. The rest of lignin not removed during cooking is removed safely during bleaching. Bleaching is carried out under more mild conditions than pulping. Thus there is no fear to degrade cellulose during bleaching if certain precautions are taken especially pH.

The alkali respectively the sulfate or Kraft process are old processes but they are still being used all over the world, sometimes with minor modifications.

Several chemical additives have been suggested to accelerate delignification and to decrease degradation of the carbohydrate fraction, hemicellulose and cellulose itself. Anthraquinone and polysulfide have been successively used. Polysulfide also reduces the amount of toxic sulfur compound and reduces odor emission. The addition of surfactant-based additives reduces surface tension and improves wetting of the raw material resulting in a quick penetration or diffusion of the chemical reagent used in cooking. Under certain precautions oxygen can be used for partial delignification. Peroxyacids have been used for pulping. Preparation of peroxy carboxylic acids, its use in pulping and properties of obtained paper have been reviewed. Peroxy mineral acids were also successfully used for pulping (Evon, 2008).

Another group of pulping processes is organosolv pulping. The advantages of organosolv pulping over conventional methods have been reported by many authors including ourselves. Organosolv pulping by different alcohols have been extensively studied in the cellulose and paper department in N.R.C., Cairo, to delignify bagasse, cotton stalks and wheat straw. Uncatalyzed ethanol and methanol pulping of bagasse resulted in a suitable pulp provided that a proper washing procedure is applied to the pulp. Alkali addition to ethanol pulping leads to an easily bleachable pulp. Bagasse pulping by butanol gave comparable results. We have studied Organosolv pulping of wheat straw using aqueous ethanol and alkali ethanol. Best results obtained in the alkaline ethanol process gave a pulp yield of 56.5% and chlorine number 3 by using 8.4% NaOH on raw material, 0.05% anthraquinone and ethanol concentration 50% at 150°C for 90 min. Cotton stalks can be partially pulped by aqueous ethanol process while the alkali process constitutes possibilities for chemical pulp quality. Screened yield was 41%, and reject was 1.5% (FAOSTAT, 2016).

Biopulping process also could be described as; Enzymes from wood destroying fungi are used to degrade lignin selectively. This biochemical process operates at low temperature and at atmospheric pressure but requires very long time. It can, then, be used as first step as partial pulping that must be then followed by mechanical or chemical pulping, but using reduced conditions (FAOSTAT, 2016).

Bleaching

Organosolv pulping using acids are the prominent choices of researchers to convert this residue into valuable pulp but in developed countries only. Developing world favours the soda and soda-AQ processes as these are economical. As a virtue of rice straw contains less lignin than wood so, rice straw requires less harsh conditions for cooking and can be easily pulped. Bleaching is a crucial step of paper making but also responsible for causing water pollution. Many studies revealed that during the process more than 500 chlorinated compounds are released that are highly toxic, bio-accumulative and carcinogenic in nature. Most of the industries over the globe switch on to the elemental chlorine free short sequence bleaching methods using chlorine dioxide, hypochlorite and hydrogen peroxide. There is an effective need of ecofriendly, economically reliable pulping and bleaching sequences in case of rice straw to eliminate the problems of chlorinated compounds in wastewater of paper mills. Such approach of using waste as a raw material with its environmentally safe processing for making paper can prove to be valuable towards sustainable growth.

Mechanical pulp which contains almost the whole amount of lignin as in the original raw material, is bleached with peroxide. Chemical and semichemical pulps are usually bleached with chlorine compounds either directly with chlorine or by hypochlorites

in one or more steps. Chemical pulps are usually bleached by a multistage process. Usually chlorine is applied in the first step followed by alkali wash then hypochlorite in the third step. This is the most conventional sequence. The hypochlorite can be divided into two steps. Before bleaching, it is necessary to determine or measure the bleachability of the pulp. Bleachability can be measured by several methods e.g., chlorine number, permanganate number and hypochlorite test. According to the result we can estimate the amount of chlorine or hypochlorite necessary for bleaching to attain a certain degree of brightness. Usually degree of brightness from 70% to 80% is required for average and high-grade paper. 85% degree of brightness or more could be also necessary in some paper types. In newsprint on the other hand even 60% brightness is sufficient.

Generally speaking, pulps from agricultural wastes, even semichemical pulps are easily bleachable. This is due to the lower lignin content in these pulps compared to wood pulps and to their open fibrous structure. Such pulps require less chlorine than wood pulps. Bleaching with chlorine and hypochlorite takes place at normal pressure and at temperatures varying from 20 to 40°C.

Environmental legislation has forced the pulp and paper industry to reduce or eliminate chlorinated organic compounds in water effluents. To satisfy this governmental demand, elemental chlorine is substituted by chlorine dioxide. This is called elemental chlorine free process or (ECF) process. Some factories have completely dispensed with chlorine and chlorine compounds bleaching and shifted to the total chlorine free process. This is abbreviated as (TCF) bleaching process. Several studies have shown that the effluents are similar in ECF and TCF especially in toxicity tests. The ECF bleaching process is preferred because of its lower capital cost compared to TCF process (Li *et al.*, 2010).

Another method for bleaching is oxygen bleaching. In fact oxygen has been used since long time for partial delignification of wood and other raw materials as a stage in the pulping process. It cannot achieve more or less complete delignification because the pulp will be excessively degraded.

Hydrogen Peroxide Bleaching

Hydrogen peroxide is a mild oxidant, which has been applied since long time in the industry especially for bleaching of mechanical pulps. It is now applied to bleach chemical pulp in order to reduce the use of chlorine in bleaching. Additives, temperature etc. play a big role in peroxide bleaching (Pan *et al.*, 2010).

Ozone Bleaching

Ozone is another oxygen-based agent producing no chlorinated organic materials in the bleaching effluent. However cellulose is susceptible to oxidation and can be easily degraded during oxygen bleaching or ozone bleaching. Several measures have to be taken to prohibit or reduce this degradation (Theng *et al.*, 2015a).

Other Bleaching Processes

These include peracids bleaching, bleaching with activated oxygen, and catalytic oxidative bleaching.

Biobleaching

This process represents a new biotechnological approach to reduce toxic effects of conventional chlorine bleaching processes. Biobleaching can be classified in two categories.

- Microbial bleaching in which growing cells are used (bacteria, yeast, fungi or algae).
- Enzymatic bleaching in which preformed enzymes are employed.

However, biobleaching has not been solely used for pulp bleaching. It should be fortified by a previous or a following chemical bleaching step (Theng *et al.*, 2015b).

Additives in Papermaking

These are the non-fibrous part in the paper furnish. In ancient days of paper making, mineral matter was added to pulp prior to sheet formation in order to increase the weight of paper. This process has been considered as adulteration. Later on it was realized that the addition of certain minerals to paper is highly beneficial. These added minerals are termed as fillers.

The process itself is called filling or loading. Fillers, when added in certain amounts, improve the opacity of paper and increase the smoothness of paper surface. Thus it improves the suitability of paper for printing. The most popular filler is kaolin or clay. Another important group of additives are the sizing agents.

Sizing makes the paper resistant to liquid penetration, e.g., writing inks. Unsized paper could not be suitable for writing. The oldest sizing agent used is rosin size. There is a lot of other additive such as dry strength and wet strength additives. Attention must be paid, that pulp alone does not make paper. Other components are needed.

Due to the high ash content in rice straw, one can more or less dispense with fillers. Due to the closed surface of paper sheets produced from this raw material, only slight sizing is needed to improve the writability. Besides using additives in paper making, the agricultural wastes pulps have to be blended with other pulp sorts, preferably soft wood pulp to ensure reasonable speed of the paper machine, and to compensate some defects in the paper (Theng *et al.*, 2017).

According to stricter environmental legislation nowadays, factories utilizing rice straw for pulp manufacture are reducing their dependence on this raw material and shift to other cellulose materials, so far that the problem of silica is not solved (Wu *et al.*, 2011).

Blending

Mixing of different pulps together is termed as blending. Addition of minerals is termed as filling. All these processes i.e., blending, and filling as well as sizing and applying other types of additives are carried out in the beater or in an extra chest. The produced mixture is called "paper furnish". This can be charged directly to paper machine.

Paper Coating

Many types of paper need to be surface sized or coated in order to modify some of paper properties or to implement new properties.

Pigment coating is one of the most important coating processes. It is used mainly for the production of printing papers for magazine, catalogues etc. Usually an aqueous mixture of pigments (e.g., clay) and an adhesive (e.g., starch) is applied to the surface of paper. When this coat is applied to a cheap dark rough-surfaced paper, one can get a paper of high brightness. In other words, the paper defects are overcome by an economic process, and the paper becomes suitable for fine printing.

Other types of coating make paper resistant to water vapor and air as required for packaging of food and beverages etc (Zhang and Hu, 2014).

The Present Status of Production of Paper and Board From Agricultural Wastes in Egypt

Rice straw was the first agricultural waste used for production of paper and board in Egypt. In the thirties cheap packaging and wrapping paper was produced from rice straw. Production of stationary paper from rice straw has begun in the early sixties. The amount of rice straw used in this industry increased steadily since that time till it reached more than 60,000 tons of pulp and more annually. However due to more and more strict environmental legislation, the utilization of rice straw has decreased.

Experimental work on laboratory scale and pilot scale has shown that difficulties, encountering chemicals recovery from black liquor could be overcome, to a great extent. Nevertheless, realization on industrial scale has not yet taken place. Apart from chemicals recovery, treatment of black liquor to decrease the (B.O.D.) before disposal in water stream has not been seriously considered up till now.

Solving the Most Difficult in Pulp and Paper Production

Recovery of Pulping Chemicals

The first step in recovery is to concentrate the dilute black liquor in order to increase its solid content. This is done by evaporation. There are several types of evaporators. Usually the liquor passes upward in vertical tubes countercurrent to the flow of steam. Vacuum also could be applied in one step or more. The concentration of the black liquor rises to about 50% solid content. The liquor is further concentrated in direct contact evaporators to a solid content more than 55% and could reach 70%. At this concentration, the liquor can be burned easily with stable combustion in the recovery furnaces. The presence of much silica in rice straw black liquor causes severe difficulties during this process. Silica precipitates at the surface of the evaporating tubes and in the nozzles leading to low heat exchange and even clogging. Therefore, desilication of the black liquor is necessary before sending the liquor to the evaporators. Several experiments and designs have been proposed for desilication.

The results were promising but the project was not completed. It should be noted that rice straw due to its open structure is easily pulpable and does not require high sodium hydroxide liquor concentration. Moreover, the price of rice straw is much cheaper than other agricultural residues. Even without recovery of chemicals, production of chemical pulp from rice straw was economically feasible. For instance rice straw cost represents one sixth of the total production cost of pulp while wood cost represents up to one-third of the cost of production.

However, production of pulp consumes about 500 tones water based on the weight of raw material. The disposal of this great amount of water directly into water stream causes environmental pollution. Other alternatives were proposed. The spent liquor instead of being discharged in a body of water can be used, as it is, for different purposes. One of the uses is the direct application of the lignin in the liquor as adhesive in brick industry.

The black liquor can also be treated easily in special installations to lower its B.O.D. demand. Then it can be safely discharged in water stream without causing pollution (Nassar *et al.*, 2017).

Recovery Furnace Operations

As seen before we have discussed each industrial operation during pulp manufacture in order to assess the suitability of agricultural wastes for full industrial manufacture of pulp. Now in the following a brief account of recovery furnace operations is given.

At first, the remaining water in the heavy liquor, coming out from the evaporators is further evaporated. The organic part of the solid matter is ignited and burnt in the recovery furnace. This part includes lignin, and its degradation products, as well as hemicellulose and its degradation products. The sodium in the liquor is converted into sodium carbonate because of the excess carbon dioxide evolving during burning. It should be mentioned that in factories using sugar cane bagasse as pulping raw material, the concentration of the black liquor charged in the furnace is usually less than average values of black liquor concentration of wood pulp.

This, however, does not affect much the profitability of the production. Many burner types are used in the furnace. The recovered chemical is discharged from the furnace bottom as a melt or smelt consisting of sodium carbonate in the case of soda process, or a mixture of sodium carbonate and sodium sulfate in the case of sulfate process. This smelt, after partial dissolution in weak dissolving liquor, is sent to the recausticizing department.

The heat generated from burning black liquor is recovered by passing hot gases into a boiler to generate steam. The amount of recovered heat is usually sufficient for all the heat requirements of the pulp factory and there could be still some heat for other uses. The recovered chemicals from the furnace are dissolved in water. The resulting liquor is known as green liquor. This color is imparted by iron compounds (Fahmy *et al.*, 2017).

Causticization of Green Liquor

This operation consists of reacting lime with green liquor after clarification. Lime reacts with sodium carbonate to produce sodium hydroxide and calcium carbonate. The causticizing reaction proceeds to about 85%–90% completion. In continuous causticizing systems the causticized liquor containing the suspension of calcium carbonate is pumped to decanters, and the clean liquor called white liquor is sent to storage tanks. From there it is pumped to the digesters for further pulping.

Land Filling

This involves the discharge of the black liquor in the earth and then covers the waste with earth.

Designating an area for land fill is an engineering project. The geological features of the area are considered, since there will be a certain amount of settling. Minimum pulp washing is necessary. Also partial evaporation to reduce water content should be considered.

The Biological Oxygen Demand (B.O.D.) must be reduced before discharging the black liquor into the sewer or water stream, the B.O.D. has to be reduced. In a primary treatment the liquor can be partially neutralized, then clarified. This takes place in big basins. The liquid is then pumped to large lagoons. The natural self-cleaning process is enhanced by aeration or by pumping oxygen in the liquid (Nassar *et al.*, 2015).

Paper Types and Properties of Paper

These are divided into physical, optical, chemical, electrical and microscopical properties. Physical properties include thickness, basis weight, tensile strength, tear strength, etc. Agricultural wastes pulps can possess high tensile strength but usually low tear strength. Optical properties include brightness and opacity. These can be tailored by bleaching ...etc. Agricultural wastes paper can be made equal in this respect to paper produced from hard woods.

Agricultural wastes are suitable for producing almost all types of packaging and wrapping paper except the Kraft liner in corrugated board as well as cement bags.

Agricultural wastes are more or less suitable for producing many types of fine paper as middle grade printing or writing paper. There are some limitations for producing newsprint from agricultural residues. Cotton linter is suitable for producing security paper such as currency and bond paper.

Paper Types

There are enormously many types of paper including the examples given before. The most common paper types are:

Newsprint, stationery papers (printing and writing), lightweight coated paper for magazine, currency paper, hygienic tissue paper (sanitary and household), paper card, solid board for boxes, wrapping and packaging paper, corrugated board. In the following some paper types are discussed in details (Anapanurak and Pisuthpichet, 1997).

Newsprint

All daily newspapers use this type because it is the most economical. All newsprint is almost made of mechanical softwood pulp. Up till now only one factory in the whole world is producing newsprint from agricultural residues. This kind of paper is lower in quality and cannot be accepted by some consumers.

Offset Paper

This is the printing paper and uncoated. This paper type is about three times expensive than newsprint. The reason is that this paper should be chemical free. It requires extensive washing during the manufacturing process as well as extensive bleaching. Filling, sizing, and other additives are required.

Opaque Paper

This is used for high quality printed paper as annual reports.

Tablet Paper

For school purposes, cheap paper with a partial ground wood content is produced for maximum economy.

Bond Paper

This paper should be durable and resistant to aging. It is usually made of rags or cotton linters.

Manifold

It is a light-weight paper used for snap-out forms.

Coated Paper

Mentioned before.

Glassine Paper

Highly beaten paper is almost non-porous and transparent. This is called (in Arabic) butter paper and is used for packaging fatty and greasy food materials.

Paper sheet formation in the laboratory involves simple operations. On the other hand, in the industry, the situation is completely different. In fact, the paper machine used in the industry represents one of the most complicated and sophisticated continuous machinery. As being reported, it consists of different parts applying different techniques for removal of water from stock. The stock flows from the headbox to the wire in a consistency of about 1%–2% fibers, i.e., about 98% water, and paper leaves the end of the machine at only 6% water or moisture content. As paper machine runs at speed of up to 2000 m/min and at a machine width up to 6 m or more, it becomes evident that production under such conditions necessitates highly technological devices to synchronize sheet transfer from each part of the machine to the next part. Any slight misfit causes the paper sheet to tear either on the wet or on the dry state.

Before going up from the laboratory scale to full industrial scale, it is advisable to carry out pilot plant scale experiments.

After call for tenders in the late fifties different pulping processes were proposed by different participants. Comparison was made between the different processes on full industrial scale regarding easier production, less technical difficulties and economic feasibility. On basis of all these steps of the study the most suitable process and most suitable conditions were chosen.

As mentioned before the presence of high amount of silica in rice straw, and consequently in black liquor, prohibits the recovery of chemicals from black liquor. Therefore, no recovery unit was established.

Despite the disposal of black liquor containing the pulping chemicals in water stream yet the process was used, and is still economic. Due to its open microporous structure and low lignin content, rice straw is easily pulpable and bleachable. In other words, the consumption of sodium hydroxide is less than half as in the case of other raw materials.

In order to find a solution for water stream pollution several experiments were undertaken. One is the desilication of black liquor before pumping to the evaporators. Pilot plant equipment has been designed and tried experimentally. Another trial was based on new design for recovery furnace. Till now neither was realized industrially.

According to stricter environmental legislation nowadays, factories utilizing rice straw for pulp manufacture are reducing their dependence on this raw material and shifting to other cellulose materials, so far that the problem of silica is not solved.

Characterization of the Rice Straw Pulp

Dry matter content of pulp was determined according to the standard method given below and cooking yield was calculated and followed by a screening process. Kappa number and the other pulp properties were measured according to the standards given (Kaur *et al.*, 2017).

<i>Analysis</i>	<i>Method</i>
Kappa Number	TAPPI T 236 cm-85
Ash (%)	TAPPI 211
α -Cellulose (%)	TAPPI 203 os-61
Pulp Dry Matter Content (%)	SCAN-C 3:78
Raw Material Dry Matter Content (%)	SCAN-CM 39:94

Physical Properties of the Pulp

- Breaking length
- Burst factor
- Folding endurance
- Brightness

Mechanical Properties of Paperboard

Strength properties: Strength properties were estimated according to the Tappi Standard Methods.

Tensile strength (Kg/mm): Tensile strength was conducted according to Tappi standard (T 494 om-01). Tensile index, the tensile strength in N/m divided by grammage.

Stiffness strength: Stiffness was conducted according to Tappi standard (T 489 om-08) This procedure is used to measure the stiffness of paper and paperboard by determining the bending moment in gram centimeters necessary to deflect the free end of a 38-mm wide vertically clamped specimen 150 mm from its center line when the load is applied 50 mm away from the clamp.

Taber Stiffness: Units are defined as the bending moment of 1/5 of a gram applied to a 3.81 cm wide specimen at a 5 centimeter test length.

The Present Status of Production of Paper and Board From Agricultural Wastes in Egypt

Rice straw was the first agricultural waste used for production of paper and board in Egypt. In the thirties cheap packaging and wrapping paper was produced from rice straw. Production of stationary paper from rice straw has begun in the early sixties. The amount of rice straw used in this industry increased steadily since that time till it reached more than 60,000 tons of pulp and more annually. However due to more and more strict environmental legislation, the utilization of rice straw has decreased.

Experimental work on laboratory scale and pilot scale has shown that difficulties, encountering chemicals recovery from black liquor could be overcome, to a great extent. Nevertheless, realization on industrial scale has not yet taken place. Apart from chemicals recovery, treatment of black liquor to decrease the (B.O.D.) before disposal in water stream has not been seriously considered up till now.

Future Prospects

The present annual consumption of different paper and board types in Egypt is till now much higher than the amount produced locally and has surpassed 500,000 tons annually. The utilization of more rice straw in future depends upon finding a suitable solution for the disposal problem of black liquor. It is possible to fulfill the environmental requirements by one or more methods. Lowering the B.O.D. before disposal of the black liquor in water stream might be reasonable. However, desilication of the black liquor before combustion in chemicals recovery furnace may be the best method. This needs further research.

Conclusion

Rice straw was transformed into pulp and paper through semichemical pulp in high yield easily. Either coarse grade pulp or fine grade pulp can be obtained by semichemical pulping. As shown earlier, the lignin content of these residues is low and much lower than lignin of wood, this facilitates delignification i.e., pulping. Moreover, the open structures of agricultural residues make them more accessible to the chemical reagents used in cooking. The reagent molecules diffuse and penetrate quickly and deeply in the cell wall fine structure. Thus, this makes agricultural residues more pulpable than wood.

Introduction

The environmental impact of plastic wastes has been recently put on the top of the agenda of each government politics. There are different ways by which the challenges related to plastic waste can be significantly overcome. These approaches include: innovative design for recycling process that makes us sure even more sophisticated packaging are appropriately recycled, development of new packaging materials which have higher efficiency to protect products while are still easily recyclable, development of biodegradable packaging materials which meet all the requirements of conventional materials, improving the collection strategies to reach more reliable techniques for handling plastic wastes, and encouraging use of recycled polymers by setting new standards development (Ragheb and Miller, 2018). Biodegradable materials are attracting much attention due to polysaccharides environmental issues and the fact that petroleum resources are finite. Food packaging is considered the main application of green polymers (Oever *et al.*, 2017). This article focuses on three various types of bio-based polymers having unique properties in order to efficiently discuss the suitability of these polymers as food packaging materials.

An Overview of Polymers

Fossil-Based Polymers

A chemical compound synthesized from repeating structural units through polymerization is called a polymer (Mirabal *et al.*, 2013). Petroleum and natural gas as fossil feed-stocks are used to produce fossil plastics or petrochemicals. The formation of fossil feed-stocks takes millions of years (EIA, 2018). About 7% of these resources are converted into polymers like polypropylene (PP), polyethylene (PE), polystyrene (PS), polyethylene terephthalate (PET), and others. Although these materials are presently and predominantly produced from fossil feedstocks, they can also be bio-based which are made from biomass (Oever *et al.*, 2017). Fossil-based polymers known as conventional polymers exhibit excellent properties like high transparency, barrier, and mechanical characteristics. Their production causes the environment to be disturbed due to increasing the effect of gases like methane, SO₂, nitrous oxide, and raising the level of CO₂ in the ecosystem which finally results in disbalance in climate pattern and subsequently, devastating disasters will occur. Various harmful gases including alkenes, alkanes, aromatic and chlorinated hydrocarbons are emitted during incineration of synthetic polymers (Ghuttora, 2016; Ashok *et al.*, 2016; Mirabal *et al.*, 2013).

Green Polymers, an Alternative to Fossil-Based Polymers

Green polymers or environmentally friendly polymers can be produced from renewable or synthetic materials (Fig. 1).

There is a false controversy between green polymers and petroleum-based polymers. According to several incorrect arguments, oil-derived polymers are environmentally unfriendly while polymers produced by organisms are considered as green. It has to be noticed that petroleum-based polymers can move towards a sustainable situation raising petroleum-derived compounds like aliphatic, aromatic copolymers can also be considered a starting point to produce biodegradable polymers which have technical properties similar to those of polyethylene (Belgian Plastics & Rubber Institute, 2006), and can be synthesized through altering the microstructure and composition to fulfill particular requirements. These materials offer an alternative to the conventional polymers used in various applications (Chauhan *et al.*, 2013). Green polymers cause no disadvantage to the environment since no hazardous substances like chemical residues or toxins are produced as byproducts (Ghuttora, 2016). Green polymers are categorized into Synthetic polymers and bio-based polymers which are totally or partially produced from natural polymers such as proteins, polysaccharides, and lipids; and poly-blends made from a mixture of bio-based and synthetic polymers, or biopolymer blends (Cheng *et al.*, 2013; Weber *et al.*, 2002).

Renewable and Bio-Based Materials

Renewable feedstock refers to the provision of feedstock collected from natural resources which are replenished rapid enough as being used. It means unlike petroleum that forms after millions of years, the resources of bio-based feed-stock renew very fast as new crop plantation balances harvesting, which means they have a high regeneration rate (Oever *et al.*, 2017; Ivankovic *et al.*, 2017).

There is contradictory and unclear information regarding biodegradable and/or bio-based materials. The term bio-based relates to the source of the material whereas the term biodegradable shows the material can be decomposed depending on its chemical structure. In fact, materials considered as bio-based are not necessarily biodegradable or compostable. A bio-based material is defined

as a product partly or wholly obtained from biomass, a material of biological origin. However, some polymers like PLA containing building blocks derived from sugars are also considered as bio-based products. Most of these bio-based materials have certificates proving they can be utilized in food-contact applications (Ivankovic *et al.*, 2017). The carbon content of bio-based materials and the bio-based content of a product can be measured according to the standard methods, e.g., the EU or ASTM standards (EN 16640 (2015), and D6866 respectively), which are based on ^{14}C (Carbon-14, or radiocarbon, as a radioactive isotope of carbon) content measurement to evaluate the biogenic carbon content (Oever *et al.*, 2017). This measurement is based on the fact that petroleum-based materials like gas and oil do not contain ^{14}C due to radioactive decay, while bio-based materials take up ^{14}C from the atmosphere and therefore contain this component (Bradley, 2010; Guzman *et al.*, 2011; Ivankovic *et al.*, 2017).

Biodegradability and or compostability or even disposing of procedure after use can be made clear to the consumer using labels and logo's, by linking a certification system (Table 1).

Environmental Impact

Conventional polymers, although very useful, cause damage to water resources, environment, and the whole ecosystem. Accumulation of conventional polymers has led to the mitigation of arable land and releasing gases by burning, which induced researchers to develop biodegradable polymers (Ghuttora, 2016; Ivankovic *et al.*, 2017). Many economic and social benefits will be brought by reducing the environmental cost of packaging waste. Substitution of petroleum-based polymers with bio-based polymers leads to the reduction of greenhouse gas emission and non-renewable energy use. However, land-use change may have a negative influence on reducing greenhouse gas emission (Oever *et al.*, 2017).

End-of-Life Options

The type of polymers and the processing infrastructure determine the end-of-life solution. Certified biodegradable polymeric materials can be digested on agricultural land and even can be industrially or home composted (Oever *et al.*, 2017). The end-of-life options are entirely dependent on the region where these materials are recovered. According to the type of biodegradable and bio-based materials and the application they are used for, the most appropriate end-of-life solution is determined. Apart from all the options reported for conventional polymers, various biodegradable and bio-based polymers can also be composted. Some of the biodegradable polymers are appropriate for domestic composting, and through industrial or home composting they will be decomposed by 90% within a maximum of 6 months. According to EN 13432 (2000) standard, these biopolymers qualify as compostable polymers (Belgian Plastics & Rubber Institute, 2006). Compostable packaging materials have a potential to collect food waste which is converted to compost through the composting route (Ghuttora, 2016; Lucas *et al.*, 2008; Shah *et al.*, 2008).

Sustainability

Sustainability is the requirement to manage the resource base, by which we assure ourselves of sharing the average quality of life by future generations. Therefore a sustainable material involves a non-subtractive quality of life (Oever *et al.*, 2017). The major aspects required to design a sustainable product are outlined in Fig. 2.

The term sustainability is meaningful when all sustainability aspects have been considered, and the specific product has been clearly compared to other products (Oever *et al.*, 2017). In the case of biopolymers, the plants are grown by farmers. After polymerization, biopolymers are converted to final products which are eventually transported to the wholesalers, retailers, and consumers. After all, composting or recycling are the end-of-life options which do not leave any toxins and nature's balance for sustainability is maintained (Ghuttora, 2016).

Durability

Durability refers to the power of a product to keep its efficiency for a long period without remarkable deterioration. The durability of a polymer depends on its chemical structure and the conditions the polymer is going to be subjected. Opposite to biodegradable materials, petroleum-based materials are considered durable. However, the lifespan of some biodegradable materials such as PLA can be as long as 10–20 years at indoor conditions, although they are biodegradable at industrial conditions via composting process. Some bio-based polymers like bio-PET and bio-PE also indicate the same durability as a petroleum-based PET and PE (Oever *et al.*, 2017).

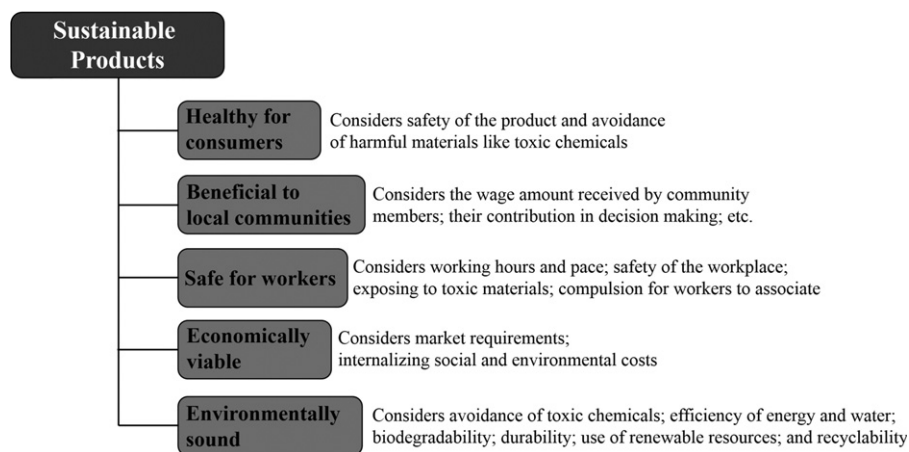

Fig. 2 Major aspects to design a sustainable product.

Costs

In general, biodegradable and bio-based polymers are high-priced on a weight basis compared to petroleum-based polymers. This higher price can be due to a higher density of most bio-based polymers. However, there are still exceptions like PLA for which the thickness of the polymer can be reduced due to the higher stiffness of PLA compared to PS, which causes the price of this material to decrease. Moreover, unlike the price of petroleum-based polymers which changes by oil price fluctuations, the price of bio-based polymers are more stable. It is foreseen that bio-based polymers prices will drop under the effect of economy of production scale, conversion and logistics (Oever *et al.*, 2017).

Food Packaging

Packaging is defined as a product used to protect, hold and deliver goods. Packaging materials should be carefully selected to meet legislation, safety, and functionality conditions and other requirements determined for various food packaging applications. The main task of food packaging is protective against microbial, chemical and mechanical impact. Moreover, packaging keeps the freshness and nutritional value of the product. The main application field of biodegradable and bio-based polymers is for food packaging (Bradley, 2010; Ivankovic *et al.*, 2017; Oever *et al.*, 2017).

Bio-based polymers which are identical to petroleum-based polymers such as bio-PE and bio-PET are applicable for the same applications. Cellophane, PLA, and Starch-based polymers with unique properties are the most common bio-based polymers used for food packaging. These kinds of materials same as petroleum-based polymers have to comply with the regulations related to food safety and have a certificate proving they are allowed to be used for food packaging especially in food-contact applications (Ivankovic *et al.*, 2017; Oever *et al.*, 2017; Siracusa *et al.*, 2008).

Type of Bio-Based Polymers Suitable for Food Packaging

As shown in Fig. 3 bio-based polymers suitable for food packaging are categorized based on their resource and production method. Commercial bio-based food packaging applications are also presented in Table 2.

Polymers directly isolated from biomaterials

These polymers comprise polysaccharides, proteins, and lipids, which are frequently presented on the market. The main feedstock used to extract these polymers are plants, domestic and marine animals. Polysaccharides like starch, cellulose and chitin; and proteins like

Fig. 3 An overview of bio-based polymeric materials.

Table 2 Commercial bio-based food packaging applications

	<i>Food packaging applications</i>		
	<i>Cups and Trays</i>	<i>Bottles</i>	<i>Films</i>
<i>Starch blends</i>	Fruits and vegetables, cups used for coffee	N. A	Fruits and vegetables, grocery bags
<i>Biodegradable polyesters</i>	Fruits and vegetables	N. A	Frozen foods, grocery bags, fruits and vegetables
<i>Cellulose</i>	N. A	N. A	Candy wrapping, fruits, and vegetables (e.g., tomatoes and peppers), meat, fish, cheese, butter, bread, coffee
<i>Starch PLA</i>	N. A	N. A	Fruits and vegetables (e.g., potatoes and carrots)
	Fruits and vegetables, bakery, salad, dairy products, meat drinking cups, ice cream	Wine bottle capsules, short shelf life products and juices	Fruits and vegetables, bread bags, using barrier laminates can be used for long shelf life products
<i>PHA</i>	Frozen foods	N. A	Fresh meat

Note: Oever, M., Molenveld, K., Zee, M., Bos, H., 2017. Bio-based and biodegradable plastics: Facts and figures: Focus on food packaging in the Netherlands. Wageningen Food & Biobased Research, Institute Within the Legal Entity Stichting Wageningen Research. Report 1722.

casein, whey, collagen, and soy protein are the most common biopolymers listed in this category which are used alone or mixed with poly(lactic acid) or other synthetic polyesters. The cellulose-based paper is the most prevalent packaging type used in the food industry, although cellophane as regenerated cellulose film and cellulose acetate are used for this purpose as well (Ivankovic *et al.*, 2017).

Polysaccharides

Polysaccharides may contain two or more sugar diagnosed as hetero-polysaccharides or may be composed of a single monosaccharide considered as homo-polysaccharides. Pullulan, curdlan, levan, and bacterial cellulose are homo-polysaccharide comprising linear chains, whereas gellan, and xanthan is hetero-polysaccharides (Oner, 2013). It has to be noticed that acyl groups, inorganic residues, and amino acids are other elements which may be attached. There are nearly 40 different monosaccharides which produce polysaccharides through making a wide variety of structures (Ghuttora, 2016). The main structural polysaccharides playing an effective role in biopolymer production are described in this section.

Starch

The most common new materials used to produce starch biopolymer are green plants such as wheat, rice, corn, and potato. Availability and low cost of starch make it the most acceptable biopolymer. Different types of bags and sacks, hot-formed containers, and trays are made using starch-based biodegradable polymers. Polystyrene and polyethylene are successfully replaced with starch-based materials (Bradley, 2010; Ghuttora, 2016). Starch can be blended with other materials in a proportion of about 30%–80% based on its application. Fossil-based biodegradable polymers like PLA or PHA/B (polyhydroxyalkanoate/butyrate) are used as the most common copolymers. These starch blends are fully biodegradable however partially bio-based. Besides, the starch may be blended with fossil-based polymers like polypropylene to produce durable polymers. Starch-based plastics have a higher density than conventional plastics which makes them less price competitive (Bradley, 2010; Ghuttora, 2016; Ivankovic *et al.*, 2017).

Pulping native starch with cellulose fibers is performed to make compostable cups and trays through the hot-pressing method. The melting point of starch is higher than the temperature in which starch decomposition occurs, which causes this polymer not to be thermally processed. In order to make thermoplastic starch (TPS), an extruder is used to process native starch under controlled conditions of pressure, temperature, shear, and water content, during which crystalline structure melts, an inter-molecular rearrangement happens by swelling granules, and semi-crystalline polymer transforms to the amorphous structure with highly enhanced processability. The final resin composition can be provided through integration of additives. Plasticizers are used to mitigate intermolecular hydrogen bonding and subsequently to stabilize the product. However, there are still limitations with TPS including limited mechanical properties and a high level of hydrophilicity that should be improved (Ivankovic *et al.*, 2017).

Biodegradable starch-based plastics

Starch-based plastics are made from starch and compostable polyesters (PLA, PBS (polybutylene succinate), PCL (polycaprolactone)). The blending of polyesters with starch caused water resistance and improved mechanical and processing properties. Starch-based plastics usually contain less than 50% of starch and are applied where biodegradability is important such as service ware, garbage bags, and agricultural products. These products can provide feedstock while containing organic waste. These materials can also be biodegraded in the soil, freshwater, marine environment, and anaerobic digestion. The main factor determining whether these materials can be used for food contact applications is the type of component blended with starch because some of these components can easily migrate (Bradley, 2010; Ghuttora, 2016; Ivankovic *et al.*, 2017; Oever *et al.*, 2017).

Starch-based films

Starch-based films are used as a monolayer or in combination with barrier films as laminates for packaging applications. These films can be translucent, but they are not a good option for applications where transparency is required. Combination of starch films with flexible polyesters like PBAT (polybutyrate adipate terephthalate) results in the high flexibility of these materials. These films are appropriate for grocery bags in which barrier properties are not required, and starch-based films are good alternatives to PE. BOPP (biaxially oriented polypropylene) can be replaced with starch-based films if an outer layer made from PLA is used. Starch-based films can also be used in barrier laminates made from cellophane in order to make them heat stable (Oever *et al.*, 2017).

Starch-based trays and other thermoformed products

Starch-based trays are structured as a rigid foam which is not transparent and only used for the applications where barrier properties are not required. Mechanical properties and the end-of-life options are important for these trays. In order to improve thermoforming properties and rigidity, the addition of PLA in blend composition can be effective; whereas, in order to increase flexibility, application of biodegradable polyesters is useful (Oever *et al.*, 2017).

Cellulose

Cellulose is a highly polar polymer composed of glucose units with strong mechanical properties. Polymer chain configures in a different way than what is observed in starch, which provides an opportunity to make this polymer stronger because of forming strong hydrogen bonds. Hydrolysis resistant of cellulose is higher than starch due to the mixed morphology of cellulose. Cellulose extraction was a difficult process with expensive pre-treatment which caused alternative extraction methods to be developed. Enzymatic hydrolysis process is used to isolate cellulose from biomass with the help of genetically modified hydrolysis enzymes (SB), such as exoglucanases, endoglucanases, and β -glucosidase. (Chee *et al.*, 2010; Ghuttora, 2016). After cellulose purification, it can be chemically modified to manufacture cellulose derivatives having improved properties (Bradley, 2010; Ivankovic *et al.*, 2017). However, bulk production of cellulose derivatives costs much. Uncoated cellulose films are a good barrier to aromas, flavor, and bacteria, and highly permeable to water vapor. Natural attributes of cellulose films can be refined through coating, metalizing, and laminating processes which cause them to be prepared for specific applications. The most effective coatings are synthetic coatings. However, bio-based coating materials can also be used (Ivankovic *et al.*, 2017).

Cellophane films

Cellophane film is produced through acetate substitution which reduces moisture sensitivity and increases transparency and gloss, while results in less biodegradability (Shen *et al.*, 2009). Different cellulose esters can be manufactured, but only cellulose acetate is currently used for food applications like fresh products and baked goods (Bradley, 2010; Oever *et al.*, 2017). Rather stiff, and highly transparent cellophane films have a small share in the market, however, for decades, they have been used especially as candy wrapping. They are also used as the glossy transparent cover on tea boxes. Cellophane as a biodegradable barrier film is suitable to be applied for manufacturing laminates (Oever *et al.*, 2017).

Chitin and chitosan

Chitin as the second most abundant polysaccharide is found in marine invertebrates such as shrimps, crabs, shellfish, insects, and some fungi and yeasts. Chitin contains units of N-acetyl-D-glucosamine. Deacetylation of chitin results in chitosan production. Chitin and chitosan are non-toxic and eco-friendly renewable polymers with no solubility in water, due to the formation of intermolecular hydrogen bonds, and no antigenic properties; besides they have excellent biocompatibility (Cheba, 2011; Ghuttora, 2016). Both are utilized to manufacture biodegradable food packaging and an edible coating which prolong the shelf life of products especially fresh fruits and vegetables (Zhao and Mc Daniel, 2005). Chitosan has poor water resistance and mechanical properties which make producers to blend chitosan with other polymers like starch in order to improve these properties. Good antimicrobial properties of chitin and chitosan make them useful as a biodegradable food packaging in order to prolong the shelf life of foods (Chiellini, 2008; Ivankovic *et al.*, 2017).

Proteins

Proteins are divided into two categories based on their origin including plant proteins (such as soy, gluten, zein, potato, and pea) and animal proteins (like collagen, casein, whey, and keratin). Numerous functionalities of proteins make them proper to be modified to create a polymer. Protein-based polymers, except for keratin, are sensitive to humidity which can be solved by blending or lamination. To date, there was no protein-based plastic commercially utilized for food contact applications. Isolated soy protein is the most common plant protein applied to produce biodegradable food packaging (Bradley, 2010).

Soybeans

Isolated soy protein-based films are weak and moisture sensitive which can be improved by incorporation of stearic acid in a proportion of about 25% (Lodha and Nteravali, 2005). It has been recently reported that blending soy protein with glycerol, K-carrageenan, or gellan gum is useful to produce biodegradable or edible soy protein-based packaging trays (Mohareb and Mittal, 2007). Barrier properties, especially to moisture, have to be considered to produce such packaging before coming across a great application in the future, due to the hydrophilicity biopolymers mostly have. Protein-based films are expected to be extensively applied as edible films in the future (Ivankovic *et al.*, 2017).

Lipids

Lipid compounds like glycerides and wax are mainly used to supply hydrophobicity in food coating structures. They efficiently prevent water-vapor transition through edible films. The functional properties of packaging films contained lipids are extensively influenced by lipid characteristics including the degree of saturation, physical state, structure, chain length, the shape of crystals, and distribution (Aydin *et al.*, 2017).

Polymers produced by chemical synthesis using bio-based monomers

In theory, all polymer materials previously used for packaging can be substituted with the types synthesized from renewable monomers. However economic viability can be a question (Kobayashi, 2010). Poly(lactic acid) (PLA) is the most prevalent polymer synthesized using bio-based monomers. Bio-based sources can also be used to prepare monomers applied for conventional petroleum-based polymers (Ivankovic *et al.*, 2017).

Poly(lactic acid) (PLA)

Polymerization of 2-hydroxypropionic acid (lactic acid) leads to produce an aliphatic polyester named poly(lactic acid). Synthesis of lactic acid is conventionally performed using acetaldehyde and hydrogen cyanide. However anaerobic fermentation of carbon substances by certain fungi or bacteria can be an alternative to this process. The new materials used for this fermentation is foreseen to move towards agricultural waste. Low and high molecular weight PLA can be produced through lactic acid condensation and ring-opening polymerization of lactide, respectively. However, the low-molecular-weight PLA is not used commercially. Utilizing racemic lactide leads to produce an amorphous structure which is unsuitable for packaging (De Vlieger, 2003). Two forms of D- and L-lactic acid naturally exist. The optically-pure monomer can be provided by fermentation using a suitable lactobacillus, which subsequently allows producers to enhance the properties of PLA polymer by controlling the combination of D-PLA with L-PLA. The best combination for packaging application is the proportion of 90% from L-lactide and 10% racemic D, L-lactide (De Vlieger, 2003). The application of PLA can be extended by blending with other polymers (Bradley, 2010).

Some specific properties which make PLA attractive for food packaging applications are its stiffness, transparency, gloss, processability, printability, and excellent aroma barrier. Moreover, mechanical properties of PLA as a rigid material is comparable with polyethylene terephthalate (PET) and polystyrene (PS) (Ashok *et al.*, 2016; Bradley, 2010). There is no food safety concern about PLA used for food contact applications. Therefore it can be used in a wide range of packaging products (NatureWorks, 2016). Stiffness and strength of PLA can be improved through combination with other biodegradable or bio-based polymers which causes cost reduction as well (Ivankovic *et al.*, 2017).

PLA can be used to package different type of products including aqueous, fatty, and acidic foods below 60°C, and acidic drinks below 90°C. Besides, considering that PLA is grease resistant, it is suitable to pack viscous and oily liquids. Moreover, dry products and those having limited shelf life can be preserved using PLA. Although PLA is appropriate for beverages, it has to be noticed that PLA is not a good barrier to oxygen, water vapor, and carbon dioxide which makes it unsuitable for carbonated drinks (Shen *et al.*, 2009). PLA is fully compostable and biodegradable. PLA is not home compostable and does not degrade in a landfill, sea water, and soil. Besides, if sorting facilities are available, PLA can be converted back to its monomer lactic acid. It can also be physically recycled (Shen *et al.*, 2009).

PLA film

PLA can be used as a homo-material or as laminates (barrier film) for food packaging. However it is not flexible and besides is rather sensitive to tearing. BOPLA films can be used as an alternative to biaxially oriented PP (BOPP) films. In this application, BOPLA is more advantageous due to its higher water vapor permeability; and they are industrially composted with vegetable and fruit waste. Without barrier materials added to the PLA layer, this bio-based polymer cannot be used to pack water sensitive products stored for a long period. These sensitive products are currently packed in films made from PE. By application of PLA mixed with barrier materials in laminates and/or using AlOx or SiOx technologies, other compostable materials holding good barrier properties will be constructed which are used for a wide range of applications. These methods cause the industry to be able to use PLA for rather a long shelf life foods (Oever *et al.*, 2017).

PLA trays

PLA trays can be used as an alternative to PS trays to pack fruits. Moreover, thermoformed cups made from PLA are varied suitably for dairy products instead of PS cups. The thickness of the cup can be significantly reduced because of the high stiffness of PLA and besides it can be composted without the need to separate its remaining content. Foamed PLA trays are also useful where reduction of cup weight is the main issue. The appearance of the bottles produced from PLA is similar to PET bottles. However high water permeability of PET does not allow the PET to be replaced with PLA in applications needing long shelf life (Oever *et al.*, 2017).

Other PLA packaging products

PLA teabag is an innovative product which does not need to be separated from tea waste for being industrially composted. Conventional paper-based teabags contain up to 30% PP fibers to facilitate heat sealing, which is not compostable. Today, most of the compostable coffee capsules are made from PLA. EPLA as a foam structure is used for various applications and is industrially compostable and safe to use for food contact applications (Ivankovic *et al.*, 2017; Oever *et al.*, 2017).

Biodegradable polymers made from genetically modified organisms

Genetic engineering and genetic modification are generally employed to improve fruit yield, alter the composition of the plant, and/or enhance plant resistance to insects or pesticides (Gould *et al.*, 2016). However, some environmental groups believe that genetically modified organisms (GMO) can be harmful to human health, conventional crops; and therefore its application has to be abandoned (Oever *et al.*, 2017).

Various types of microorganisms including *Alcaligenes*, *Bacillus*, *Azotobacter*, *Rhizobium*, *Halobacterium* produce large quantities of renewable materials. These materials are accumulated by bacteria as a carbon reserve and source of energy. PHAs and bacterial cellulose are two main polymers produced through this route (Ivankovic *et al.*, 2017).

Polyhydroxyalkanoates (PHA)

Polyhydroxyalkanoates (PHAs) are hydrophobic polyesters which may have different properties depending on the monomer building blocks that result in a wide variety of PHA. PHA may be rigid, brittle or rubber-like polymer depending on the carbon source and the bacteria type (Ashok *et al.*, 2016). The bacteria type and the feed are the main factors determining the general structure of monomer units repeated in polyesters like PHA. – (CH₃)-CH₃ is the most prevalent unit repeated in the structure of naturally-occurring PHA. Poly (3-hydroxybutyrate), PHB, is a semi-crystalline linear bio-polymer recognized as a biodegradable PHA. PHB produced by bacterial fermentation of lipid or sugar is useful for food packaging. Biodegradation of PHB takes about 5–6 weeks under optimum conditions (Botana *et al.*, 2010; Ivankovic *et al.*, 2017). PHA can be an elastomeric or a thermoplastic material. Therefore its melting point alters between 40 and 180°C (Yalcin *et al.*, 2006). PHA characteristics depend on the technique used for microbial fermentation, and monomer composition (Ashok *et al.*, 2016; Kumar *et al.*, 2011; Modi *et al.*, 2011).

PHAs, like PLA, are kind of aliphatic polyesters manufactured via fermentation, however, in contrast to PLA, PHAs are synthesized directly within the microorganism. The composition and final properties of PHA polymer are associated with bacteria strain and feedstock type. Moreover, copolymerization can modify PHA characteristics. PHA as the most common polymer of this group is synthesized by polymerization of 3-hydroxybutyrate monomer.

Poly hydroxybutyrate-co-hexanoate (PHBH), and poly (3-hydroxybutyrate-co-valerate) are two main copolymers. These copolymerizations improve processability, ductility, toughness, and flexibility in the finished product (Noda *et al.*, 2004). PHAs can be converted into molded articles, films, fibers, laminates, coatings, and foams. using a conversion process. PHAs are good barriers to water vapor, which makes them appropriate for food packaging applications. PHAs are mostly applied as alternatives to PVC, PP, LDPE, and HDPE. Moreover, bio-PHAs can be utilized for food service ware (Shen *et al.*, 2009; Bradley, 2010).

Bacterial cellulose

Bio-cellulose (bacterial cellulose) is very strong and pure with good mechanical and barrier properties; however, its low yield and high cost prevent large-scale production and application of this material for bulk products (Bradley, 2010).

Conventional polymers from bio-based monomers

Different types of fossil-based conventional polymers can be made using renewable monomers which are indistinguishable from their oil-derived counterparts. One of these polymers is poly (trimethylene terephthalate) (PTT) synthesized through condensation of PDO (1,3-propanediol), and either PTA (terephthalic acid) or DMT (dimethyl terephthalate). PTT characteristics are similar to PET, and the same facilities can be used for its production (Ivankovic *et al.*, 2017; Shen *et al.*, 2009).

Polyurethanes

Polyol and isocyanate are used to synthesize polyurethane. Polyol component can be acquired from vegetable oils, while to date, isocyanate was exclusively obtained from petroleum-based feedstock (Ivankovic *et al.*, 2017).

Polyamides

Bio-based polyamides which are currently available include PA610 and PA11, both synthesized from monomers derived from castor oil. Other monomers partially acquired through fermentation of sugar can be utilized to manufacture partially bio-based PA66. Moreover, azelaic acid as a bio-based monomer derived from oleic acid is used to produce PA69 (Shen *et al.*, 2009).

Polyolefin

Bioethanol produced via fermentation process is used to manufacture polyethylene. In fact, ethylene is produced from bioethanol which is then applied to make polyethylene (LDPE, LLDPE, HDPE), PVA, PET, and PS. As the characteristics of bio-based PE are identical to the properties of fossil-based PE, conventional PE can be totally substituted with its bio-based counterpart. A proportion of about 57% of PE used in Western Europe, is applied for packaging (Schut, 2008; Shen *et al.*, 2009). As previously mentioned different types of conventional polymers are synthesized from renewable resources, among which bio-based PE is the main polymer commercially available for food packaging applications (Bradley, 2010; Shen *et al.*, 2009).

Bio-Based Food Packaging Forms

Several different forms of biodegradable packaging are produced to meet the requirements to pack various products. The most commonly used forms include edible coatings, biodegradable gels, films, bags, trays, and boxes (Ivankovic *et al.*, 2017).

Edible coatings

One of the green food packaging application is an edible coating formed directly on the surface of the food product. Edible polymers are considered as polymeric materials easily consumed by human beings or animals through oral cavity which do not give harmful effect to the health. Direct utilization of edible polymers on the product surface can provide additional protection to retain the quality and stability of the product. The requirements of edible polymers are defined according to the specific characteristics of the product feedstocks, and the alterations may occur in these properties throughout the production and storage (Kokoszka and Lenart, 2007). The loss of nutrients is prevented using edible polymers which control the transportation rate of molecular components from inside of the packaging. Moreover, these coatings slow down harmful reactions and cause the prevention of unpleasant changes in food products. Mass transport properties are measured to determine the efficiency of edible coatings (Buonocore *et al.*, 2003; Kokoszka and Lenart, 2007). The possibility of edible polymer consumption with food products is their main advantage over conventional synthetic polymers, which eliminates residues needing to be disposed of and consequently contributes to decrease the environmental effect. Edible polymers are exclusively manufactured from edible, renewable ingredients (Dhanapal *et al.*, 2012). Organoleptic properties of food products can be expanded by using edible polymers containing various ingredients such as colorings, flavorings, and sweeteners. The coating is usually performed by spraying or dipping which create a thin film on the surface of food that suppresses the gas transfer and controls the moisture loss (Dhanapal *et al.*, 2012). Four different component categories including hydrocolloids, lipids, polypeptides, and composites can be used to prepare edible polymers. Hydrocolloid films are good barriers to carbon dioxide, oxygen, and lipids, while are an unsuitable barrier to water vapor. Hydrocolloid polymers are quite advantageous to use for fragile food products because they possess great mechanical properties. Protein-based edible films are the most attractive ones due to their superb gas barrier properties compared to the polymers prepared from polysaccharides and lipids. At a very low proportion of humidity, the oxygen permeability of the films prepared from soy protein has been measured about 540, 500, 250, and 670 times less than what was reported for LDPE, starch, methylcellulose, and pectin, respectively (Akbari *et al.*, 2007).

Moreover, numerous linkages at different positions can be formed in protein-based edible films. Some requirements need to be fulfilled by edible polymers including mechanical efficiencies, high barrier properties, microbial, physicochemical, and biochemical stabilities, and nontoxicity and non-polluting effects (Bergo *et al.*, 2010; Shit and Shah, 2014). Edible films can be commercially produced through several techniques like extrusion process, compression molding, and novel electrospinning process. Different approaches like using natural extracts, modified polymers, and nanocomposites can be applied to improve the functionality of edible film coatings (Ashok *et al.*, 2016).

Active packaging

Considering demand for green packaging materials is growing, novel technologies and novel green packaging materials have been developed. Active packaging is produced by preparing composites which are blends of polymers and specific additives having various geometries like spheres, fibers, and particulates. Edible polymers can be utilized as active packaging by which consumer demand for elevated retention freshness and quality of foods will comply. Active packaging preserves the product quality by altering the surrounding conditions of the food (Ashok *et al.*, 2016).

Biodegradable gels

The extremely hydrated gels as hydrogel polymeric networks are generally applied to prevent microbial contamination (Farrisa *et al.*, 2009). Impregnating gel may show positive effects on the quality of food products and maintain specific components like beta-carotene inside the fruits. However, it has been figured out that a mixture of hydrogels diminishes the service life of some fruits, may be due to moisture migration through the surrounding area (Ivankovic *et al.*, 2017). Numerous water absorption capacity of hydrogels causes fast decay of product to be avoided because packaging material absorbs the moisture released from food products. Flexibility and brittleness of the gels should be at a certain level which makes it possible to fold these materials as desired during packaging.

Bio-based polymers used for food packaging can be produced through the approach of poly-ion complex hydrogels. Introducing mainly charge interactions instead of hydrogen bonding strengthens polymer-polymer interactions which subsequently improves the mechanical properties of biopolymer films (Farrisa *et al.*, 2009, 2011).

Biodegradable films

Biodegradable films are manufactured with the intention of substitution of polyethylene film utilized for various applications including packaging products, industrial films, and collection of organic waste. The quality of some fruits and vegetables like tomatoes will be affected by the permeability of film to oxygen and carbon dioxide. Low permeability adversely affects fruits quality. Although, when the permeability of packaging films and respiration of the fruits are compatible, the durability and quality of the product will be positively affected through prevention of contamination by insects and microorganisms (Ivankovic *et al.*, 2017;

Muratore *et al.*, 2005). The flexibility of composting programs will be increased using biodegradable films, and no harmful residues are left after composting.

Biodegradable bags

Biodegradable bags are flexible, strong, resistant to damage and breakage, and resistant to temperature and moisture alterations. The notable applications of these bags in the hydroxybutyrate food industry can be correlated with the composition of raw materials used for this production. The application of these bags can be extended to other industrial branches by using incorporation of certain additives. Moreover compared to the traditionally used polyethylene, biodegradable bags are more sustainable because upon completion of their use as packaging, they are exposed to a composting process which decomposes them to water, and carbon dioxide and no harmful or toxic substances will be created (Ivankovic *et al.*, 2017; Nampoothiri *et al.*, 2010).

Biodegradable boxes and trays

Corn is used to producing bi-oriented polystyrene with the intention of manufacturing biodegradable boxes with lids. These bags are temperature resistant (between -6°C to $+80^{\circ}\text{C}$), grease resistant, and crystal clear which provides good visibility of content (Alemar *et al.*, 2008). Biodegradation of such packaging happens after 47 days during which no harmful substances will be released in the environment.

Various fresh food products like sliced broccoli, sweet corn, tomatoes, salad, and blueberries are successfully kept inside biodegradable trays, which are brittle and resistant to moisture (Ivankovic *et al.*, 2017).

Bio-Based Polymers Challenges

There are several problems related to the commercial performance of bio-based materials compared with their fossil-based counterparts, which limit the application of these polymers for food packaging. The poor performance of bio-based materials associated with their processability, hydrophilicity, barrier properties, resistance to breakage, the properties of raw materials, and high production cost are the main challenges associated with these materials (Jang *et al.*, 2011; Ramos *et al.*, 2018). The degradation rate of bio-based polymers, alteration of their mechanical properties by time, possible interactions with food compounds, and their potential to develop microorganisms are other concerns that have to be noticed regarding bio-based polymers (Rhim *et al.*, 2013). Moreover, the use of bio-based polymers for a broad range of applications is also restricted by their inherent properties like brittleness, vapor and gas permeability, melt viscosity, and thermal stability (Ramos *et al.*, 2018).

Barrier properties

Packaging used for many foodstuffs must meet the barrier requirements especially moisture and gas resistant. Permeation capacity of bio-based polymers determines their barrier properties. Permeation capacity means the capacity of exchanging low molecular weight articles through the polymer (Kumar *et al.*, 2011). Most of the used biomaterials possess poor barrier properties which makes it necessary to apply synthetic polymers (such as EVOH) in laminate or blend films to achieve the desirable barrier characteristics. Polysaccharide-based materials are sensitive to humidity and exchange a large amount of water vapor and other polar substances when exposing to a large portion of moisture. While barrier properties to oxygen and non-polar substances like oils and flavors are acceptable at the low or middle level of humidity, water vapor permeability of starch-based materials is about 4–6 times higher than what is measured for conventional polymers. The surface hydrophilicity of these materials can be reduced through fluorinating them. The water vapor transmission rate of PLA is 3–5 times bigger than that of LDPE, PET, and HDPE. While oxygen barrier properties of PLA is better than PS but less than PET, the water vapor transmission rate of PHA is similar to the petroleum-based materials. Oxygen barrier properties of PHB is greater than PET and PP and is adequate when the film comes to fragrances and fat. Gas barrier properties in most biomaterials are dependent on the ambient humidity (Ivankovic *et al.*, 2017). Various techniques can be applied to achieve high moisture barrier properties like an external coating of water-resistant material, blending with moisture resistant materials, crosslinking using inorganic fillers, or reinforcement using natural fibers like sisal, jute (Ashok *et al.*, 2016).

Mechanical properties

One of the features distinguishing polymers from small molecules is mechanical property. The mechanical properties of biopolymers are frequently similar to the petroleum-derived polymers (Table 3).

The molecular weight, orientation, and crystallization degree are the main parameters defining the properties of biopolymers. For example, regarding PLA, heat stability and mechanical strength are improved by the orientation of biopolymer. Moreover, different proportions of crystallinity and various molecular weight result in a wide range of materials characterized from hard and strong to soft and elastic. The poorly crystallized and amorphous PLA has a shiny and transparent surface, while highly crystallized PLA indicates an opaque surface. The properties of PHA is dependent on the molecular structure and the composition of the copolymer. PHB as a thermoplastic polymer is generally hard and highly crystalline which cause its mechanical properties to resemble the isotactic PP (Ivankovic *et al.*, 2017).

Table 3 Typical mechanical properties of some bio- and petroleum-based polymers

Polymer	Young's modulus (MPa)	Tensile strength (MPa)	Elongation at break (%)	References
<i>Biopolymer-based polymers</i>				
Poly(lactic acid) PLAs	3600	49.6	2.4	Mathew <i>et al.</i> (2005)
Poly(hydroxyalkanoates) PHAs	200–3500	17–40	5–680	Sudesh <i>et al.</i> (2000)
<i>Petrochemical based polymers</i>

PLA is reasonably transparent and has acceptable mechanical properties which are comparable with those measured for fossil-based thermoplastic polymers. PLA films can also hold twists or creases which make them a good alternative to fossil-based plastics (such as LDPE, PP, HDPE, PET) in different applications. The most promising applications are rigid containers, high-value films, and expanded foams (Bradley, 2010; Shen *et al.*, 2009).

Techniques for Improving Functionality

Lamination

The properties of single biopolymers are improved by producing laminates or multilayer films. Generally, biopolymers are susceptible to brittleness, drying and mechanical forces which can be overcome by developing multilayer films based on conventional and bio-polymers. Laminate films are extensively useful to extend the shelf life of food products like fresh pasta, meats and cut vegetables (Fang *et al.*, 2005; Chiellini *et al.*, 2008). Multilayer films used as food packaging materials mostly contain several thermoplastic polymer layers to provide a combination of moisture- and oxygen-barrier, and mechanical properties. Therefore, natural packaging biopolymers are now considered to be used as a barrier layer especially to oxygen and aroma. For example, chitosan films, relative to commercial polymers, indicate a superior oxygen barrier properties while water vapor barrier property is measured low for chitosan. Therefore improvement of mechanical and barrier properties are the main advantages of these films. These multilayers easily separate in a solvent, which makes them recyclable (Shin *et al.*, 2002).

Nanotechnology

There are many reports indicating the properties of bio-based packaging materials can be enhanced using new techniques like nanotechnology as the most effective technique showing unique advantages (Armentano *et al.*, 2015; Cerqueira *et al.*, 2012; Ramos *et al.*, 2014). Nanotechnology has recently attracted considerable attention to be used to improve bio-based polymers and develop novel polymeric materials (Jochen Weiss and McClements, 2006). Nanotechnology as a new technique is used to develop bio-nanocomposites which improve mechanical performance, barrier properties, and even thermal properties of bio-based polymers (Table 4; Chiellini, 2008).

Bio-based reinforcement agents for bio-nanocomposites

Cellulose nanowhiskers

The main types of nanoscale materials obtained from cellulose and used to reinforce bio-nanocomposites are nano-fibrillated cellulose, cellulose nanowhiskers, and nanocrystalline (Velásquez-Cock *et al.*, 2014). Cellulose nanofibrils contain a bunch of molecules elongated and stabilized through the formation of H-bonds (Reddy *et al.*, 2013). Both crystalline and amorphous regions are found in these fibrils. Crystalline part of this structure can be isolated using various techniques and is known as a whisker. Amorphous region is removed through acid hydrolysis in order to extract cellulose nanowhiskers (Azizi Samir *et al.*, 2005). Incorporation of cellulose nanofibrils into bio-based polymer matrices like chitosan creates new materials with superior transparency and mechanical properties (Fernandes *et al.*, 2009). Mechanical properties of PLA films can be improved by the production of PLA-based nanocomposite films using lignin nanoparticles and cellulose nanocrystals (Yang *et al.*, 2016). Moreover biopolymers these structures cause oxygen and water vapor barrier properties to be improved as well.

Bacterial cellulose nanofibrils/nanoribbons

Although the chemical composition of bacterial cellulose synthesized by bacterial species is identical, its structure and mechanical properties are different to those of plant cellulose. Generally, bacterial cellulose possesses higher crystallinity, superior mechanical properties, moisture-barrier properties, water holding capacity, and purer nano fibrillar structure compared with plant cellulose (Fernandes *et al.*, 2009; Velásquez-Cock *et al.*, 2014). Therefore nanoribbons and nanofibrils prepared from bacterial cellulose are excellent reinforcement agents used for various polymeric matrices (Wan *et al.*, 2009; Velásquez-Cock *et al.*, 2014).

Starch nanocrystals

Starch nanocrystals as new reinforcement materials are produced by acid hydrolysis. The conditions under which hydrolysis occurs including temperature, starch, and acid concentrations, stirring speed, and hydrolysis duration should be strictly controlled (Le Corre *et al.*, 2010). Three-dimensional architecture and semicrystalline nature of these reinforcement agents make them susceptible to hot water which can result in disruption of starch nanocrystals by exposing to hot water that subsequently limits their use to prepare starch-based nanocomposites (Xie *et al.*, 2013). However, in general, it has been reported that the application of starch nanocrystals leads to improve thermal stability, mechanical performance, and barrier properties of nanocomposite structures prepared using nanocrystals are likely due to strong interactions between matrix and nanocrystals through H-bond formation (Sessini *et al.*, 2016; Garcia *et al.*, 2009, 2011).

Chitin nanowhiskers/nanoparticles

Different chitin sources can be used to prepare chitin nanowhiskers through deproteinization in a boiling potassium hydroxide solution which is followed by using a boiling hydrochloric acid solution to do hydrolysis step (Gopalan Nair *et al.*, 2003; Sriupayo *et al.*, 2005). Considering acid hydrolysis causes some of the crystalline part to convert into amorphous regions, utilization of alternative production methods of chitin reinforcement agents and the use of other techniques like sonication, ionotropic gelation, can lead to developing chitin nanoparticles having different crystallinity level (Chang *et al.*, 2010b). Moreover, these new methods may avoid unsuitable conditions like the toxicity of substances (Chang *et al.*, 2010a; Tsai *et al.*, 2008). Mechanical properties and water sensitivity of biopolymer films are improved by incorporation of chitin whiskers to biopolymer matrices (Rubentheren *et al.*, 2015; Sriupayo *et al.*, 2005). Besides, the presence of chitin nanowhiskers provides a good antimicrobial activity against *Listeria monocytogenes* (Qin *et al.*, 2016; Chang *et al.*, 2010b).

Zein nanoparticles

Various types of protein including gliadin, lectins, zein and soy proteins can be successfully applied to synthesize polymeric nanoparticles used for food applications. However, among these protein-based nano-reinforcement agents, zein is especially interesting to be used to produce nanoparticles. Zein nanoparticles can be produced through different procedures like liquid-liquid dispersion method which results in the formation of zein nanoparticles with diameter sizes less than 200 nm. It has been reported that these particles enhance nanocomposite properties including barrier and mechanical properties (Oymaci and Altinkaya, 2016).

Future Trends

Development of bio-based packaging materials depends on different factors such as the global demand for energy and food resources and legislative and political changes. However bio-based materials will be increasingly used for food packaging applications because of the environmental issues, cost of petroleum-based polymers, etc.

Next generation of bio-based materials used for food packaging applications is likely to be bio-nanocomposites. Development of bio-nanocomposites is a route to create innovative materials in the area of bio-based polymers. Nowadays a new group of

edible polymers was being developed using nano-technological procedures such as nano-encapsulation structures with the goal of the introduction of controlled release systems protecting bioactive compounds from extreme heat and humidity conditions. These systems enhance the viability and stability of susceptible active compounds. Moreover, nutritional properties of food products can be enhanced using nanoscale nutrients and additives, and delivery systems applied for bioactive compounds (Jochen Weiss and McClements, 2006). Various functional agents such as antioxidants, antimicrobials, enzymes, colorants, and anti-browning agents can be incorporated into the nano-laminate structures coating food products. In general, most of these nanocomposite materials prepared using bio-based polymers can compete both in performance and price with fossil-based polymeric materials (Shit and Shah, 2014; Akbari *et al.*, 2007).

Conclusion

According to the literature review, it can be concluded that green polymers have a great role in the food packaging industry. Biodegradable polymers are increasingly used to produce packaging materials partly due to the new strategies used to improve their properties, and partly because the price of bio-based polymers is getting more acceptable over time. Moreover, it must be noticed that novel techniques, especially nanotechnology, extensively affect the future of green packaging by improving its performance. These approaches have not only the potential to enhance biodegradation, barrier, thermal, and mechanical properties but also create new functionalities like antimicrobial properties. However, more researches need to be done in order to use these methods to tailor advanced packaging materials.

Introduction

Water is an essential part of our life on the earth and to sustain life every human being takes several liters' of water daily. All the aquatic life is dependent on water (Luo *et al.*, 2014). With increasing population day by day, the freshwater resources are decreasing quickly. Among many reasons of decline in freshwater resources, polluting of water is one of them. Surface and ground water are resources of fresh water and are vulnerable to contamination. There are various ways to make toxic and impure water. One of them is wastewater flowing out through industries. The industries like textile industries, ceramics industries, auto industries, leather tanneries, oil refineries, paper industries, cosmetic industries are draining the wastewater in the rivers, sea, canals that consist of many by-products and waste effluents (Deblonde *et al.*, 2011). The industrial waste pollutants also accompanied by some organic chemicals contain highly toxic organic byproducts, heavy metals, oils, and mineral acids. This contaminated water which is polluted by toxic hydrocarbons compound, heavy metals, toxic dyes, and metalloids is the main cause of polluting the surface as well as groundwater. For removal of these toxic materials, different methods are adopted including membrane filtration, electrodialysis, photocatalysis, adsorbent process, and nanomaterials catalytic activities.

The contaminated water discharge through industries and factories are polluted and toxic to our health as well as for agriculture and marine life. It is also the cause of irreversible degradation of the atmosphere resulting in serious health problems (Deblonde *et al.*, 2011). The leather industries, fertilizers tanneries, oil refineries, textile, paper, rubber, and agrochemicals etc. are producing wastewater that contains pollutants such as highly toxic synthetic organic compound (O.C), oils, greases and mineral acids. These compounds are very dangerous and injurious to all living organisms.

Heavy Metals and Their Toxicity

Heavy Metals

Heavy metals have a density greater than water and are easily dissolved in water and produce positive ions in the solution. Usually, the heavy metals have atomic number greater than 23 and density higher than 5 gm/cm³ (Deblonde *et al.*, 2011). Heavy metals are Cadmium (Cd), Arsenic (As), Mercury (Hg), Chromium (Cr), Lead (Pb), Nickel (Ni), Uranium (U), Aluminum (Al), and Thorium (Th). Under the controlled condition, these are useful in chemical analysis. The higher quantity than cellular metal accomplished value, these metal especially cadmium, silver, and nickel cause the toxic effects on the environment (Sheoran and Sheoran, 2006). The toxicities of three heavy metals named cadmium, mercury, and lead are very high even though their presence of 0.05 mg m⁻³ can become serious problems such as Pulmonary Edema, vomiting, nausea and affects directly to the gastric system of the humans. The specific limits of heavy metals are in different quantities.

Sources of Heavy Metals

There are two types of sources of heavy metals like primary and secondary. In nature, these heavy metals are found in the earth crust. The secondary sources of heavy metals are industry, medical and domestic wastage of water. Heavy metals primary sources summary is shown below in Table 1.

Toxicity of Heavy Metals

Out of 80 metal elements throughout the 118 recognized elements, the more toxic elements are heavy metals. These metals are soluble in the water and in food nutrients. When industrial waste water leaches into the soil and flows out through rivers and sea,

Table 1 Primary sources of heavy metals (Pb, Ar, Cd, Hg)

Heavy metals	Primary and secondary sources
Lead	Fuel combustion, oil refinery, petroleum and gasoline, auto-exhaust, lead solder food can lead plumbing pipes, lead storage paints, lead storage batteries, electrical equipment
Mercury	Antiseptic, refinery system, scientific devices, glowing light, plastic and as paints
Cadmium	Scrubber, battery, tannery system, mining equipment, electroplating machines, dyes
Arsenic	Insecticide and pesticide, wood preservative, combustion fuel, copper smelter

it turns the fresh water into polluted water. The annual casting amount of lead is 3 million tons. A controlled amount of lead is used in lead storage batteries, gasoline refineries, sanitary system and cable coatings. Cadmium is used in the electroplating system, dyes and pigments, transport objects, television equipment, a nickel-cadmium battery and solar systems (Naja and Volesky, 2009). Chromium salts and chromium-VI are very serious and injurious elements for plants and water living things. The mg/L values of toxicity for heavy metals are given in Table 2.

Heavy Metals and Their Impact on the Environment

The water extracted from industry contains polluted contamination including the heavy metals and other toxic synthetic organic compounds (Gadd and Griffiths, 1977). The origin of heavy metals is ores like iron sulfide, arsenic sulfide, lead sulfide, aluminum sulfide, selenium sulfide and gold sulfide. This metal contamination is becoming very serious now-a-days in every country especially in Asian countries like Pakistan. These heavy metals consist of cadmium (Cd), copper (Cu), lead (Pb), chromium (Cr) and their oxides. The mercury from industry reacts with dyes and chemical and converts into methyl and dimethyl mercury resulting in the cause of the toxic component. These transition rare metals exhibit biotic, aquatic, agricultural toxic and hazardous effect on human beings. The resulting symptoms cause many diseases in living organisms because of wastewater polluted water usage air spoliation, and land waste materials leaching (Barakat, 2011). The numbers of patients had been increasing in hospitals during the last 5 years. Sudden death has now become common.

Effect of Heavy Metals on Aquatic Life

Marine and other living organisms in the ocean and rivers are dependent on the water. Without water, their lives would be impossible. The wastewater including dangerous toxic metals, extracted from hospitals, industry and chemical laboratories flow through rivers, canals, oceans and as a result in sea leach out. This water in oil spillage converts definite dyes into acids. The heavy metals also present in this wastewater are soluble in water, resulting in an acidic solution. The solubility of mercury is due to its compound formation (Tyagi *et al.*, 2017).

The mercury elements leach out from industry waste effluents are deposited in rivers reacted directly to microorganism anaerobic reparations of marine. Consequently, the dimethyl mercury and methyl mercury result in marine life to toxic food web and affects the ocean life. Likewise, mercury the other heavy metals are soluble in water and becomes the sources of acidic salt solution in water and when this water is used by the fishes, amphibians, brush, and plants even for man chores is also dangerous to their health. Thus, the food chain of marine life is also poisoned and toxic (Wang *et al.*, 2008).

Effects of Heavy Metals on Human Beings and Agriculture

Overdose of heavy metals leads to hazardous and poisoned impacts on human beings. Within limit these metals are suitable for human, the excessive and recess amount can also become the cause of even the death of human (Jeong *et al.*, 2013). The symptoms to the food web of man are peptide disarrangement, diarrhea, tremor, haemoglobinuria and many other serious diseases as discussed and shown in Fig. 1.

The agricultural uses of this wastewater that flow out through the rivers and canals toxins the fertility of soil which leads the fresh water into an acidic solution that is to irrigate the fields by the peasants. The highly poisoned metals are absorbed in soil and water and ultimately injected into the grains during their development (Khulbe and Matsuura, 2018). As a result, when the water is planted to crops most of the plants are dead and some of them go through the growth process. These are deadly harmful to health and to pollute the environment. High blood pressure, Anemia, Vomiting, Irritation, Gastric system, Immune system disorders, Blindness, Headache, Nausea, Asthma like diseases are increasing day by day due to drinking the wastewater and by taking the poison food.

Table 2 Representation of toxicities of heavy metals in Mg/L

Heavy Metal	Mg/L	Toxicities
Arsenic (Ar)	0.05	Skin infection, cancer, vascular diseases
Cadmium (Cd)	0.01	Headache, renal and cortex problems
Chromium (Cr)	0.05	Headache, diarrhea, dermatitis
Copper (Cu)	0.25	Liver diseases, insomnia
Nickel (Ni)	0.20	Asthma, coughing, carcinogen, nausea
Zinc (Zn)	0.80	Thirst increasing, neurological disease, headache and anxiety
Lead (Pb)	0.06	Destruction of brain nerve, kidney, and nerve related diseases
Mercury (Hg)	0.0003	A cause for kidney, circulatory, nervous problems

Fig. 1 Illustrates the effects of heavy metals on the human beings resulting in diseases. Reproduced from García-Niño, W.R., Pedraza-Chaverri, J., 2014. Protective effect of curcumin against heavy metals-induced liver damage. *Food and Chemical Toxicology* 69, 182–201.

Conventional Process for Removal of Heavy Metals

The adsorption process, chemical decomposition, ion exchange, electroplating, floatation is the conventional process to remove the heavy metals effluents. The chemical precipitation process, as described in Eq. (3.1), is a process using at a large commercial scale.

where the ions M^{2+} and (OH^{-}) are dissolved in the solution to form the impure $M(OH)_2$ that are insoluble in water. This reaction is strongly dependent on the pH level of the solution. Lime water consists of calcium hydroxide, due to low cost and high facilitated it is used frequently. It is used in excessive amounts as in 1000 mg/L. but, it requires the high availability of metal. The low amount cannot perform the mechanism. Another method like electroplating is used to pass the current to flow through the hydrous solution. The resulting ions move towards their respective electrodes like cathode and anode. Consequently, the resulting products in the form of metals crystal formed. But, it is a corrosive method. Ion exchange is a process to exchange the cations and the anions in the atmosphere. The ions, that are transferred to air is in the form of hydrocarbons.

Filtration Process

Membrane filtration, based on the ultra-filtration, nano-filtration and reverse process of osmoregulation, are the processes to remove the heavy metals effluents from the contaminated wastewater. The ultra-filtration uses the semi-permeable membrane to separate all pollutants having size up to 5–20 nm. In literature measured values of free-pollutants by this process is up to 95% especially for Cu and Zn. The filtration process is repeated to 5–6 times. It is done by the amino group that is present in the resulting suspension. The amino group action is presented in Eq. (3.2).

The functional group with donor atom is attracted towards the metals. By reacting with metals, the product is the formation of a complex structure which is strongly dependent on pH as shown in Eq. (3.3).

To remove the cadmium and chromium metals, the $ZnAl_2O_3-TiO_2$ is being used widely and attained the precipitation of 93% of Cd and 86% of Cr. This can filter by the ultra-filtration membrane. The membrane filtration can pull the metals up to 80%–90% removal from wastewater at a concentration rate of 10–12 mg/L with pH value level of 5–9.5. Due to fouling it has a hazardous effect on the membrane caused by the turgor pressure, and flux low rate. The process is also performed for reverse osmosis and

nano-filtration for copper and cadmium. The osmosis process is suitable to achieve 98%–99% concentration of free metals (Sivakumar *et al.*, 2015).

Electrodialysis

Electrodialysis is another process in which current is passed through the solution to separate the ion from the membrane. Membranes are the ionic solution comprising of the ion species. When the current passes through the solution, the ions move to their respective electrodes. Polyvinyl fluoride-membrane and perfluorosulphonic-Nafon-117 membranes are used as cations. When flow rate is increased, the separation rate decreased. At more than 500 ppm concentration, separation is ceased. The Electrodialysis (ED) process was established in chemistry to remove the toxic metals from solution. This process requires the precautionary measurements like contaminated air avoidance, specific temperature, voltage and pressure control.

Photocatalysis

In photocatalysis, the sunlight falls on the aqueous solution of the semiconductor. This light energy is converted into the charged particle if the band-gap is less than the light energy. These charges are removed by the semiconductor wafers like TiO_2 , ZnO , CdO , etc., responsible for oxidation and reduction as shown in Eqs. (3.4–3.6) as an example.

The UV-light has to irradiate on the prepared solution to transform it into ionic solution and then the redox reaction started (Hashmi *et al.*, 2013).

The chromium reduction is possible by using the UV-radiation on titanium dioxide catalyst in combination with Neodymium catalyst. The Nd ions that make a layer on the TiO_2 surfaces act like a layer deposited on the electrons. The separation of positive and negative charges increases the oxidation-reduction reaction and the recombination reaction does not take place. The electron acts like donor and chromium as an acceptor to the TiO_2 . Powder TiO_2 limitation is improved by the process of immobilization. The immobile process converts the toxic chromium Cr(VI) to non-toxic chromium (III) under UV-characterization.

Adsorption Process

The adsorption process is a mass exchange mechanism between solution (water) and soil/surface. Different agricultural waste adsorbents, industrial by-product adsorbents, natural material, synthesized biopolymers, and less-cost adsorbents are used to remove the heavy metals from wastewater. The sorption method consists of three basic processes: (1) transfer of pollutant on the adsorbent substrate/surface, (2) adsorption on the surface and (3) transport within the adsorbent molecule (Tchounwou *et al.*, 2012).

The zeolite material is a natural ion-exchange particle. Among the zeolites, the clinoptilolite is used for selection of Pb, Cd, Zn, and Cu. Cation ability for this zeolite is dependent on the pre-treating conditions. The pH factor is very important in the selection of adsorption of the heavy metals. For removal of Cr, NaA zeolite is used at pH 7. The copper and zinc are absorbed by the 4A-zeolite at neutral and basic pH values. Manganese is adsorbed at the alkaline pH. Magnetically modified zeolite (MMZ) adsorbs the Pb(II) and Zn(II) at pH 5–10.

Research revealed that rice husk, pecan shells, jackfruit, maize cob, and hazelnut cover have properties of the removal of heavy metals. The process to remove heavy metal using agricultural products is called bio-sorption. Rice shells are used to extract the heavy metal Cr(VI) at pH 2, Potato peel charcoal adsorbed the Cu(II) and Zn(II), and coconut shell charcoal is used to remove the Cr(VI) (Bourke *et al.*, 1995).

Remedies of Heavy Metals Using Nano-Particles

Carbon and oxide-based nano-particles have the capability to adsorb the heavy metals from the aqueous solution. The carbon nanotubes (CNT's) are the nano-range materials that are widely used in different fields of life. To remove pollutants from the wastewater, the nanotechnology is playing a vital role. The adsorption, redox, photo-catalyzation, and size exclusion process are the widely used processes to remove the heavy metals ions from the solution. Size exclusion is one of the processes used to remove the impurities in the form of filtration as discussed before. The adsorption processes the nano-particles such as CNT's, FeO_3 , charcoal, graphene, MnO_2 , TiO_2 , ZnO_2 are being used to remove the heavy metals. These particles are present in the form of particles, tubes, powder etc. These nanomaterials are low cost and reliable particles to eradicate the heavy metals (Borchers *et al.*, 2013). Recent research has shown that the nanomaterials as adsorbents are used in the purification of water. The polluted particles that are characterized are Ni^{2+} , Cr^{3+} , Cr^{6+} , Cu^{2+} , Cd^{2+} , Co^{2+} , Hg^{2+} , Pb^{2+} , As^{3+} , As^{2+} , Th^{2+} , Eu^{3+} , Sr^{2+} , Zn^{2+} and U^{6+} . Moreover, adsorption capacity of different nanomaterials shown in Fig. 2. These materials like carbon active, CNT's, graphene, with oxide materials like ferric oxides, manganese oxide.

Fig. 3 Hydroxyl ion reaction mechanism for the removal of pollutant. Reproduced from Ameta, R., Solanki, M.S., Benjamin, S., Ameta, S.C., 2018. *Photocatalysis Advanced Oxidation Processes for Waste Water Treatment*. Elsevier, pp. 135–175.

Bismuth Nano-Particles

The bismuth nanoparticles show the electrical, optical and non-resistive properties (Soltani and Entezari, 2013). These are Bismuth vanadate, Bismuth oxyhalides, and Bismuth chalcogenides. Bismuth Chalcogenide is photoelectric compound with 6th group elements. These are represented as Bi_2E_3 (O, O, S, Se, Te, O, S, Se, Te, Te) and consist of bismuth oxide (Bi_2O_3), bismuth sulfide (Bi_2S_3), bismuth selenide (Bi_2Se_3) and bismuth telluride (Bi_2T_3). These materials are semiconductor materials with specific bandgap. When the sunlight or the electrical light source falls on the polluted water, these are converted into ions to extract heavy metals from aqueous solution.

BiVO_4 exists in three stages namely; monoclinic scheelite, tetragonal scheelite, and the tetragonal zircon. Through the photocatalytic process, the harmful products are removed. Photodegradation of hydrocarbons occurs when a photocatalyst absorbs the light of suitable wavelength and converts the substrate into the cation and anions. Hydroxyl ion in water then reacts to remove the pollutants. The mechanism is shown in Fig. 3.

Strategies to Increase the Photo Catalytic Properties of BiVO_4

To improve the efficiency of BiVO_4 nanoparticles, there are three methods. These are (1) doping, (2) heterojunction and (3) catalyst deposition. These methods are performed by the earth-crust elements that are in abundance (Niu *et al.*, 2015). When these three processes are performed for hexavalent heavy metals ion like Mo^{6+} , Cr^{6+} , W^{6+} , then the doping of Mo^{6+} is found to be more significant at photo-current generation and 2-times higher than electrode potential. Further, the resistance is decreased and an increase in efficiency is observed to be about 25%. To increase the efficiency of Mo^{6+} - BiVO_4 , the WO_3 was deposited on the layer of BiVO_4 . This has to increase the photocurrent about 50% with 3 times higher generation of photocurrent. The observed photocurrent for this heterojunction was 2.4 mA/cm² with weight 60%–90% (Asghar *et al.*, 2013).

Conclusion

Herein, numerous sources of wastewater including industries, factories, mining and tanneries in the form of organic compounds, heavy metals, dyes, and chemical textures have been reviewed and discussed. The heavy metals like Pb, Zn, Cr, Hg etc. were found to be more hazardous for human livings, aquatic system, wild animals, plants and crops. With the passage of time, numerous techniques like filtration, electrolysis, electrodialysis were used to treat the hazardous wastewater that contain heavy metals. However, high cost and low efficiency limited their wide use. The photocatalysis, being a green approach, was observed to be the most efficient and stable technique to completely degrade the heavy metals present in wastewater.

Structural Integrity Assessment of Bamboo for Construction Purposes

Paul O Awoyera, Covenant University, Ota, Nigeria

Adeyemi Adesina, Concordia University, Montreal, QC, Canada

© 2017 Elsevier Inc. All rights reserved.

Introduction

With the possibility of using different materials to support loads, it is essential to assess the structural integrity of the materials so as to prevent failure. Structural integrity of a material can be defined as the capacity of the material to withstand a predetermined load without failure during its service life. The loss of structural integrity in a material leads to failure of the material. Failure of the material can be as a result of deformation, fatigue, and fracture.

Assessment of the structural integrity of materials used for construction applications is very essential, as this would help the designer in making appropriate material selection for specific uses. Structural integrity assessment can be carried out on building materials, such as concrete, steel, wood, and bamboo.

Generally, the structural integrity of a material depends mainly on its mechanical properties, such as strength, elasticity, and durability. Assessment of this integrity is based on the specific application of the materials, as this varies depending on the estimated load the material would carry. For instance, the mechanical properties of concrete to be used for a rigid pavement are different from the properties of the concrete that would be used for a column of a high-rise building. For safety reasons, the maximum load carrying capacity or stress of a material should be higher than the design load or stress. The ratio of maximum load capacity or stress of the material to the design load or stress is called safety factor.

This article focuses on the structural integrity assessment of bamboo for construction purposes. Bamboo is one of the most frequently used materials in the field of construction; it is used in very sensitive areas, such as scaffolding and making concrete formworks. However, due to the significance of the support that bamboo provides during construction, its failure can result in structural collapse or leaving the structure in an unserviceable state.

Bamboo can compete with building materials, such as concrete, wood, and brick, and can be used for several structural applications (Sá Ribeiro *et al.*, 2004). Therefore, its properties and performance must be determined, to ensure proper application.

Significance of Bamboo as a Construction Material

Bamboo is a plant in Plantae kingdom, and it's one of the world's fastest growing plants. Bamboo grows in areas around the equator as shown in Fig. 1.

On the other hand, owing to the clamor to reduce the CO₂ footprint caused by the production of other building materials, such as steel and concrete, bamboo is a good material in this regard. As can be observed in Fig. 2, bamboo requires about one-eighth of the energy required to produce concrete of the same strength, about half that of wood, and one-fiftieth that of steel. Therefore, the use of bamboo is a great way to reduce the construction industry's CO₂ footprint, and its strength and application flexibility also complement this advantage.

Not only is the strength and sustainability of bamboo a great choice for structural construction purposes, the plant can be harvested every year, which gives it an edge over wood, which requires an average age of 15 years to be harvested.

The properties of bamboo vary based on the type of species and climate of where they were grown (Ghavami, 2008), and assessing their structural integrity would help to determine their suitability for structural application. The parts of bamboo play a critical role in its properties, when using it for structural application.

Common Uses of Bamboo in Construction

Bamboo can be used for a variety of application, and construction has been its primary application (Lobovikov *et al.*, 2007). However, most of these applications have been limited to nonengineered construction, leading to inappropriate structural applications. A few examples of structural applications are briefly elaborated.

The use of bamboo for scaffolding over decades is common in Southeast Asian countries, such as China, India, and Thailand (Janssen, 2000). A typical bamboo scaffolding is shown in Fig. 3. The ability of bamboo to resist winds caused by hurricane (Chapman, 1996) has been one of the reasons why the scaffolding application is more common. However, its durability and lack of standards has limited the broad adoption of using bamboo for scaffolding (Jayanetti and Follett, 2008).

Bamboo has been used in the construction of simple suspension bridges. A study concluded that the best way to use bamboo for bridge construction is by using a short trestle framework (Jayanetti and Follett, 2008). However, Laroque (2007) suggested the possibility of using bamboo for girder and suspension bridge construction in his study. A sample pedestrian bridge built using bamboo is shown in Fig. 4.

Fig. 1 Bamboo grows in areas around the equator, with about 1.4 billion tonnes annual worldwide production, resulting in \$2.5 billion in international trade in 2005. Reproduced from Lobovikov, M., Paudel, S., Piazza, M., Ren, H., Wu, J., 2007. World bamboo resources: A thematic study prepared in the framework of the global forest resources assessment 2005. In: Food and Agriculture Organization (FAO) of the United Nations, Rome, Italy.

Fig. 2 Embodied energy of bamboo and other building materials. Data from Salcido, J.C., Raheem, A.A., Ravi, S., 2016. Comparison of embodied energy and environmental impact of alternative materials used in reticulated dome construction. *Building and Environment* 96, 22–34.

The use of bamboo has been limited to construction of mostly small houses and community buildings, such as schools and community centers. These houses are found in rural communities, and are of simple design as the construction is by locals (Jayanetti and Follett, 2008). An example is shown in Fig. 5.

However, in the urban areas, there are large structures built with bamboo. A good example is the Church without Religion in Colombia, shown in Fig. 6, which was designed by Simon Velez, a famous Colombian architect. Velez also designed other bamboo structures, such as a bamboo bridge in China and the ZERI Pavilion.

Bamboo can also be used as a roofing member for a building. It can be employed in different ways, such as using it for making truss systems, rafters, tiles, or as covering (Jayanetti and Follett, 2008). Fig. 7 shows a roof made using bamboo.

Structural Integrity of Bamboo

Failure of bamboo structures can lead to several devastating situations, such as injuries or economic losses. This failure would be as a result of bamboo being stressed beyond its strength limit. Bamboo being a natural material makes its properties vary from one sample to another. Therefore, it is essential to determine the factors that affect its strength limit and overall structural application.

These factors can be classified into physical properties and mechanical properties; the physical properties directly affect the mechanical properties of bamboo. However, it should be noted that it is difficult to compare bamboo based on these properties, as there may be difference in the composition of samples, and testing methods.

On a general note, one study (Kaminski *et al.*, 2016) has shown that the bamboo plant will possess good structural integrity if it tends to:

- grow locally in abundance,
- be stronger than other local species,
- have a large diameter (50–200 mm),

Fig. 5 House made with bamboo. Photograph by Kubo, B. Housing with bamboo. Available at: https://commons.wikimedia.org/wiki/Main_Page (accessed 11.06.17), distributed under a CC-BY 2.0 license.

Fig. 6 Church without Religion in Colombia. Reproduced from Vélez, S. Arquitectura vegetariana. Available at: <http://www.simonvelez.net/> (accessed 11.06.17).

- grow relatively straight,
- mature quickly (3–5 years),
- be slightly more resistant to insects and fungi, having lower starch content, although bamboo may also be cured in boron mix to enhance its resistance to attacks, and
- be less susceptible to splitting.

These attributes form the basis for selection of a particular species of bamboo for traditional construction works.

Bamboo Plant Parts and Features

Canes and nodes

The cane is the long tubular part of the bamboo plant, and this has been used for various applications, such as beams and columns. It has been used effectively for these applications by filling the first node with concrete or cement to ensure it stays fixed in the ground to prevent splitting of the cane (Minke, 2012). The node also has a huge influence on the structural integrity of bamboo, because it increases the capacity of the bamboo to resist buckling or splitting. As a result, it is necessary to perform

compression tests on a complete section of bamboo, with the load being situated between two nodes. There are short fibers in the bamboo nodes (Richard, 2013), which are responsible for its rigidity.

Culms

The culm of a bamboo is the hollow part; a typical structure of the culm is shown in Fig. 8. However, not all bamboo species have hollow culm. Fiber density of bamboo increases from the inner wall of the culm to the outer part. The high density and presence of silica in the outer wall of the culm serve as a protection for bamboo, but can lead to construction tools getting blunt when used on it (Janssen, 2000).

Fig. 9 Relationship between diameter and elastic modulus of bamboo. Reproduced from Laroque, P., 2007. Design of a low-cost bamboo footbridge. MSc Thesis, Massachusetts Institute of Technology.

The culm normally serves as a structural support, and pathway for water and sap movement in bamboo. The culm is made up of 10% vessels, 40% cellulose fibers, and 50% parenchyma tissue (Janssen, 2000). As the bamboo grows, the parenchyma tissue hardens, and the fibers are responsible for the strength development in the culm (Richard, 2013).

Properties of Bamboo

Physical properties

The age of bamboo significantly affects its strength, and the optimum age is between 3 and 4 years, therefore bamboo younger than 3 years or older than 5 years should not be used for structural construction purposes. Liese and Weiner (1996) also observed that there are lesser strength properties in bamboo when it is older than 5 years.

The size of bamboo plant is another factor that can influence its strength characteristics. In terms of structural applications, the slenderer the bamboo is, the better are its mechanical properties. Therefore, the thinner bamboo canes would have better mechanical properties compared to the bigger ones. This would be as a result of the microstructure of the bamboo, as the proportion of the silicate external skin is greater in thinner bamboo canes than bigger ones (Laroque, 2007). An illustration of how the size affects the strength properties is shown in Fig. 9.

The size of a bamboo can also be described using the outer diameter, as it determines whether the bamboo is slender or not. As can be seen in Fig. 9, the diameter is very essential when using bamboo for structural application, as there is an optimum cross-section for elastic modulus, when the bamboo is in tension or compression.

Bamboo fiber density is another important property. The thickness of the cell wall and fiber diameter determines the fiber density of the bamboo. This can equally be quantified by the specific gravity of the bamboo, and it has been found to affect its mechanical properties (Janssen, 2000). The density of bamboo is between 700 and 800 kg/m³, and approximately 60%–70% of the culm tissue, with 60% at the outer wall of the culm, and between 10 and 15% at the interior wall (Richard, 2013). The bamboo fiber density increases with the culm's height (Amada et al., 1996).

Janssen (2000) shows the relation between stiffness and strength of some building materials to their density. It can be seen in Fig. 10 that, compared to other building materials, bamboo has a high and similar value for both ratio of strength and stiffness to density. The optimal density for bamboo has been found to be between 520 and 820 kg/m³, but outside this limit, there would be a significant reduction in its compressive strength (Laroque, 2007).

Mechanical properties of bamboo

The mechanical characteristic of bamboo is mostly influenced by its physical properties. However, the level of effect may vary depending on the type of physical properties. Bamboo is a good structural material used for construction; it is strong in both tension and compression (Laroque, 2007), unlike a building material, such as concrete, which is strong in compression only, but weak in tension.

Compressive strength

The compressive strength of the bamboo is essential in assessing whether it can be used for construction purposes. There are various factors that determine the strength of a bamboo plant. For instance, strength properties are higher in bamboo between

Fig. 10 Effect of material density on the strength and stiffness. Reproduced from Janssen, J., 2000. Designing and building with bamboo. INBAR Technical Report 20, Beijing, China.

3 and 4 years old, but outside this age bracket, bamboo is found to possess a lesser strength characteristic (Sattar *et al.*, 1990), and it was also reported that the compressive strength of bamboo increases with culm height.

The compressive strength of bamboo is estimated to be 30.7–42.2 MPa (Tomak *et al.*, 2012) or 0.094 times the density (Janssen, 2000). The accompanying failure pattern during compression test is lateral bulges and vertical cracks. Lignin has been found to have a huge effect on the failure resistance of bamboo under compression, because it provides rigidity in the bamboo cell wall and it does not rot easily. So, it will require much energy and time before the tangential expansive forces generated could lead to critical tangential strains on the bamboo (Arce-Villalobos, 1993).

Modulus of rupture

Also, another important characteristic to be assessed in bamboo is the modulus of rupture. It should be noted that modulus of rupture is not the same as modulus of elasticity. Compared to modulus of elasticity, modulus of rupture is the amount of a material's strength before it ruptures. In bamboo, the modulus of rupture (bending stress) is related to the fiber length (Janssen, 2000), and it decreases with the culm height (Tomak *et al.*, 2012). The modulus of bamboo was reported to be between 69.5 and 102.7 MPa (Tomak *et al.*, 2012), and also estimated to be 0.14 times its density (Janssen, 2000). Also, Fig. 11 shows the relationship between flexural strength and modulus of different wood products.

Young's modulus

In addition, there is need to evaluate the Young's modulus of bamboo, which helps to measure how stiff a particular bamboo sample is, and it can also be used to determine elastic properties of bamboo when it is in compression or tension. The Young's modulus along the fibers depends to a large extent on the number of vascular bundles per area (Janssen, 2000). Therefore, the Young's modulus of bamboo can be determined by measuring the fraction of fibers across the bamboo wall thickness (Janssen, 2000), and then using the fraction (Ghavami *et al.*, 2003; Li and Shen, 2011). The relationship between the Young's modulus and the density of bamboo and some other building materials is presented in Fig. 12.

Tensile strength

Bamboo is known to possess a good tensile strength, but it is necessary that this property be examined in a species before being used. Just like in a typical wood, the direction of force application on the fiber affects its strength properties. The fibers present on the outer part of the bamboo have high tensile strength compared to other parts of the bamboo (Laroque, 2007). Compared to the compressive strength, the tensile strength of bamboo is almost the same for its entire service life. However, the tensile strength of bamboo has been found to differ widely between different species. The nodes of the bamboo exhibit lower tensile strength compared to other parts due to their twisted fiber (Amada *et al.*, 1997).

The tensile strength of bamboo varies, depending on whether it is assessed along fiber length or across the fiber.

When the tension force is applied across the fibers, just the lignin matrix withstands the stress, which results in cracking and splitting failures (Richard, 2013). Bamboo tends to fail at a specific transverse strain of approximately 0.001 (Arce-Villalobos, 1993) when loaded transversally.

Shear strength

Shear strength is the property of a material to resist the forces that cause the internal structure of material to move or slide against itself. Bamboo, having a hollow cross section, has less cross-sectional area to resist shear force compared to similar building material, such as timber. There are two shear planes in bamboo: shear plane parallel to the fibers and shear plane across the cross section of the culm (Richard, 2013). Bamboo exhibits a critical shear stress of 2.2 N/mm^2 (Janssen, 2000) at the neutral axis.

Fire resistance

Though this is not a strength property, it is essential to understand the fire resistance of any construction material, because it is a norm that a material tends to diminish in strength after being exposed to fire. So, fire resistance can be indirectly related to strength. Bamboo canes have a good fire resistance capacity, because of their high density and presence of high silicate acid content in its outer skin (Laroque, 2007). Large-scale tests have shown that bamboo is able to last longer compared to a wood system that is unprotected but loaded the same way. Bamboo has also been graded as hardly combustible but flammable by DIN 402 (building behavior of building materials).

Method of Making Bamboo Joints

One of the challenges associated with the use of bamboo as a structural construction material is designing for joints (Laroque, 2007) that are capable of transferring forces in the whole structure effectively, without bulging at the joint. The method of joining bamboo together or with other material is critical. Therefore, the most accurate technique must be employed to ensure the resulting bamboo structure is capable of carrying its designed load, throughout its entire service life.

The cylindrical shape of bamboo and presence of nodes at different intervals makes the design of connections and joints for bamboo difficult. An ideal joint for bamboo members must take into account the geometric form of bamboo and also the varying size of the bamboo among culm of various species and along the culm itself.

Traditional methods

These types of connections involve the use of available natural materials, such as bamboo stripes, palm or coconut fibers, and rattan, to join the bamboo components together (Laroque, 2007). When these natural materials are used to join bamboo together, it is referred to as lashing. Lashing is the most commonly used method of joining bamboo members, as it is cheap, easy to use, and takes minimal time to do (Jayanetti and Follett, 2008). The fibers can be used by passing it through drilled holes in the members, or by simply knotting the members together (Laroque, 2007). However, most of the existing traditional joint methods lack strength and deform easily (Janssen, 2000). Therefore, depending on the bamboo application, careful selection of the type of joint to be used has to be determined.

Since joining bamboo effectively requires much consideration during construction, more research and development of existing methods of bamboo jointing, can enhance the possibility of a wider adoption of bamboo for construction purposes.

However, it is important to avoid using a fresh cut bamboo for construction. Bamboo needs to be completely dry before it can be used; this will ensure there is no shrinkage of its diameter when used in joinery. Otherwise, using a fresh cut bamboo can cause loss and weak joints after a few weeks of erection. The drying process of bamboo can best be done in air, and not in the sun, because sun drying bamboo could create cracks in its wall due to the rapidity of drying.

Bamboo Failure Modes

The common failure modes in bamboo include fracture, fatigue, tensile tearing, and creep. When bamboo is subjected to loading, it fails by fracture of the fibers connecting the weaker lignin, thereby resulting in longitudinal splitting of the bamboo (Janssen, 2000). However, bamboo possesses excellent elastic properties (Sá Ribeiro *et al.*, 2004), such that when it is subjected to bending, it tends to return back to its original straight form, despite being fractured. This ultimately shows that there is enormous benefits to bamboo over other building materials, and this can be an advantage for ensuring structural stability during hurricanes or earthquakes.

Fatigue failure can set in when a bamboo member resists higher load than the design load, which leads to cracks forming at the stress points along its length. However, when an axial load is imposed on a weaker bamboo cane, this could result in bamboo tensile tearing.

Bamboo has a better resistance to creep loading than materials like timber. When loaded with its outer culm-wall in tension, bamboo exhibits a larger modulus of rupture, lower apparent modulus of elasticity, and a lower residual strength when compared to specimens with their outer culm-wall in compression (Gotttron *et al.*, 2014).

Enhancing Resistance of Bamboo to Failures

To ensure that forces and stresses are transferred within the structure appropriately, proper joints, and end caps must be used. Improper transfer of forces and stresses in the structural system can lead to cracks and possibly failure of the bamboo

structure. Therefore, to ensure a safe connection between the bamboo members or the foundation, the first node of the bamboo can be filled with cement with a metal rod attached to the end of the bamboo (Minke, 2012). On the other hand, it was also suggested that the end of the cane can be reshaped into cone, using cement or epoxy to wrap a steel wire around it.

Need for Bamboo Standard Regulations

Compared to building materials, such as concrete and steel, bamboo is less regulated, and this has made its acceptance and usage very low. Due to these shortcomings, the technicalities of bamboo usage are not well understood by constructors, and consequently, bamboo is mostly referred to as an inferior building material (Richard, 2013). Therefore, the development of standards for testing and design of bamboo for structural construction can promote its acceptance and also ensure that it is used properly and safely. Standards ensure the protection of the users, environment, and regulation of the production, and also serve both the social and technical contexts. Current tests that have been standardized for bamboo properties are shown in Fig. 13.

Summary and Conclusion

Assessing the structural integrity of bamboo for construction purposes is essential to ensure that its usage aligns with the required applications. This gives an indication of the whether bamboo is capable of carrying its current design loads and future loads without failing or bending redundantly during its service and functional life. This assessment can also lead to potential cost savings and better application of bamboo for construction purposes.

Not only is bamboo suitable for structural application because of its strength and light weight, its esthetic, cost, low environmental impact, and accessibility makes it a great choice for construction purposes. Bamboo being a natural material is both its greatest asset and weakest point, as it is sustainable but the properties of similar bamboo are not generic.

Though the mechanical properties of bamboo are above par, it is necessary to treat bamboo against fire, and attacks from termites, beetles, and fungus. Bamboo is more susceptible to attacks than common building materials like concrete and steel.

More research and development is still needed in the field of bamboo technology to understand its properties more and its effective uses for structural purposes.

Sustainability and Recycling of Bamboo for Engineering Applications

Paul O Awoyera, Covenant University, Ota, Nigeria

Emmanuel I Ugwu, Michael Okpara University of Agriculture Umudike, Umuahia, Nigeria

© 2017 Elsevier Inc. All rights reserved.

Introduction

Bamboo, also known as *Bambusa vulgaris*, is a general nomenclature for various types of giant grasses. There are nearly 1500 species under 87 genera of bamboos worldwide (Ohnberger, 1999), and these species can exist in diverse forms and shapes (see Fig. 1). Bamboo grows mainly in the tropics especially in regions like Africa, Asia, and Latin America. It has a height ranging from some centimeters to above 30 m and stems ranging from 3 mm to above 25 cm.

Ashby and Ashby (2016) described bamboo as an exceptionally fast-growing plant, allowing harvesting within 4–7 years for construction purposes. Its stem usually collapses and decays after reaching its longevity, but this depends on the climate conditions as well as the species of the plant. However, no matter the conditions of the environment, the bamboo plant still tends to survive. Interestingly, bamboo is one of those rugged plants that can grow in poor soils, and as a result it is a useful plant for degraded soils (Hunter, 2003). In the same vein, bamboo forests have ecological and environmental functions, in terms of soil erosion control, land rehabilitation, water conservation, and carbon sequestration (Tu *et al.*, 2013). However, various species of bamboos affect soil characteristics in various ways. Arunachalam and Arunachalam (2002) reported that bamboo increases the microbial biomass in the rhizosphere zone by providing a large root surface, which significantly helps in increasing the fertility of the soil. Meanwhile, aside from enriching the soil fertility, bamboo also reduces microbial activities and soil enzyme activity (Tu *et al.*, 2013).

There are significant roles that bamboo plays in terms of climate change adaptation and mitigation, in addition to safety net provision to forest-dependent communities vulnerable to the effects of climate change (Kumar, 2014). The bamboo plant is able to act as cover for soil, and also stabilizes riverbanks and reduces soil erosion.

The Japanese, Chinese, West Indian, and Indo-Chinese communities, use bamboo for different daily activities, because it is a strong plant, and also due to its hollow stems, excluding the nodal partitions. Also, in a developing country like Nigeria, there is spatial distribution and availability of bamboo in various localities, only that the quantity is yet to be ascertained. The versatility, beauty, and strength of bamboo, both in its natural and finished states, are enormous. This makes it one of the most consumed plants all over the world. Studies have shown that bamboo is a useful raw material for the production of original items for domestic and commercial uses (Xiaobo, 2002; Bansal and Zoolagud, 2002). Fig. 2 shows parts of a bamboo plant and some of their common uses.

Some of the unique attributes of bamboo are that it is fast growing and attains maturity in a short period, and in fact, its fiber is stronger than that of wood fiber. These characteristics make bamboo an important tree for solving wood shortage problems in developing countries. The problem of wood shortage in some developing countries has been solved via the use of bamboo on a small-scale for furniture making, fencing, and shed construction, just to mention a few. However, despite the use of bamboo in most rural settings, the paramount use of bamboo is for making scaffolds during building construction. When bamboo is used as scaffolds in building, it tends to provide structural support for the building, so, it is very important for the bamboo plant to attain maturity before it can be used for making scaffolds. The more mature a bamboo plant is, the more strengthened it becomes (Chung and Yu, 2002).

Bamboo has many benefits, which include its ease of cultivation and harvesting, as well as its renewable resource nature. It equally has a very high tensile strength that can be compared to mild steel, since it can withstand forces as great as 231 kN (Environmental Bamboo Foundation, 2011).

Background to the Use of Bamboo in Construction

The use of bamboo as a construction material began many centuries ago. However, despite the popularity and continuous usage of bamboo, it is still regarded as a nonengineered construction material. There is a wide availability of bamboo across the globe, due to its rapid growth and regeneration; this makes it a potential sustainable alternative to the conventional engineered building materials, especially in the regions where it is readily available.

Bamboo is known to be one of the oldest construction materials, used since ancient times. The incorporation of bamboo as a construction material started in the regions where plant growth is abundant, including Africa, South America, and most especially Southeast Asia. The worldwide bamboo habitat is shown in [Fig. 3](#).

Buildings using bamboo look back on an ancient tradition. Since ancient times, bamboo material has been used in a surprisingly large number of applications. For instance, in building architecture, there are numerous applications of bamboo in

Fig. 4 Bamboo used as a skeletal building. Reproduced from KATI, 2012. Uses for bamboo in sustainable building. Available at: <http://www.greenbuild.org/new-construction/uses-for-bamboo-in-sustainable-building/> (accessed 04.06.17).

several types of construction. There are skeletal buildings that are strictly bamboo houses as shown in Fig. 4. These buildings are just raised floors having main posts that are anchored firmly to the ground. This ensures the stability of the bamboo building. Generally, the structural stability of the skeletal bamboo building is extensively provided by its posts, which are anchored in the ground. Thus the only loading considerations for its construction are mainly the vertical and horizontal forces that are acting on the building; these forces include wind load or pressure, load resulting from rainfall on the roof, live loads from moving objects in the building, and lastly the dead load from the weight of material used for its construction.

The increasing world population, which is still estimated to attain 9.7 billion people by 2050 (United Nations Department of Economic and Social Development, 2015), creates a notion for natural material like bamboo to be adequately utilized in construction, as a measure to sustain the convention materials. Bamboo is obviously a much needed alternative to a variety of construction materials. Over the years, the application of bamboo for structural purposes across the globe has ensured a lot of development and sustenance in areas, such as:

- using bamboo to construct small houses for homeless people or internally displaced people from war zones and natural disasters;
- reducing the effect of natural disasters and their resulting damages; and
- helping to sustain the growing socioeconomic gap in populations around the world.

Although, despite the visible impact of bamboo as a tool for ensuring sustainability in the construction field, it is still mostly regarded as an inferior material by stakeholders in the built industry. However, Richard (2013) attributed this assertion to a lack of understanding, as well as a lack in engineering standardization among the users.

Also, since ancient times, the simplest roof covering has been formed using bamboo shingles that are as long as the rafters. An example of such roofing system is presented in Fig. 5. The shingles are produced by splitting bamboo canes into halves along their length, while the diaphragms are removed. As shown in the figure, the bamboo cane halves are threaded to the ridge and positioned, such as in the “Roman tile fashion.” The shingles are not fixed at the eaves and are held in position by their own weight.

Notably, from the ancient times until now, bamboo has mostly been used as a scaffolding member, even before the introduction of the tubular steel scaffolding system. A multistory building under construction having bamboo scaffolding system is shown in Fig. 6. Bamboo has an excellent load-bearing capacity, coupled with its relationship with its weight, so this has made it a suitable material for the construction of safe scaffoldings, in buildings ranging from medium height to high-rise buildings. In the same vein, ladders are also made from bamboo stems, often found in India. In addition to the use of such ladders for climbing high places, it is also used in India to make small carriers for transporting the dead from one place to another.

A variety of footbridges and bridges have also been constructed over the years from bamboo material. Bamboo has a good elastic property even more than timber or any similar material, which ensures its usefulness for this purpose. Although, it will require some structural expertise before it can be used for large bridges, mainly because there is need to put into consideration measures that takes care of its side effects, such as vibration, bending, and at times twisting. As it is commonly known, footbridges

and bridges are structures that are exposed to the weather, no matter how they are covered. As a result, they tend not to last long, like bamboo skeletal buildings. The applications of bamboo as a material for footbridges and bridges range from its usage as poles that are placed across a ditch to the twin suspended framed truss that spans over a river about 30–50 m wide, or as tied battens that hold poles together and also act as a load distributor so that the load on a single pole is transferred to its surrounding members. In such bridges, the ends of the poles are pinned to the ground, thereby ensuring that they are secured against turning and displacement. In China, bamboo has been a popular material for the construction of suspended bridges. An example is the Qian-Xian suspended bridge (Fig. 7), which was constructed before AD 960 and it is still standing today. Although, it has been continually maintained to keep it in use to date.

In a more advanced application, bamboo was used for construction of the world's largest dome in India. The dome was built in 2010, and has a diameter of 34 m. This dome is an illustration of the interaction existing between the urban and the rural areas of India, thereby showcasing the various sections of the Indian culture, like the faith, language, and culture. The dome structure, during and after construction, is presented in Figs. 8 and 9, respectively. Also, in modern construction, bamboo has been used as a flooring material (see Fig. 10).

Bamboo is a naturally existing resource, and it is therefore essential to ensure its sustenance and standardization, in order to foster a better performance of its structural components. As a material, bamboo has unique and promising attributes that can lead to its general acceptance and consumption in the construction industry.

Uses, Recycling, and Sustainability of Bamboo

Bamboo as Reinforcing Member in Concrete

Due to the increasing cost of steel reinforcement bars, and coupled with a bid to reduce the persistent reliance on conventional reinforcement used in concrete, bamboo is currently one of the considered alternative materials used in place of steel. In recent years, bamboo has been processed into typical reinforcement bar sizes, which are systematically arranged and embedded in concrete instead of the conventional steel bars. A comparative evaluation of the flexural behavior and deformation pattern of concrete members reinforced with bamboo, rattan, and twisted steel rebars was performed by Adewuyi *et al.* (2015). From that study, it was reported that the bamboo bars are suitable rebars for non-load-bearing and lightweight-reinforced concrete flexural members. Bamboo has even been used as concrete reinforcement in various studies. An investigation by Ikponmwosa and Fapohunda (2015) explored the behavior of foamed aerated concrete beams that were reinforced with bamboo strips. According to the study, the deflection of beams decreased with increasing area of the bamboo splints, and it was also reported that the failure load decreased with an increase in area of bamboo at the tension zones. Another related study (Karthik *et al.*, in press) has indicated that bamboo strips could be a good alternative to steel bars in structural beams. Similarly, other studies (Ikponmwosa and Adegbite, 2011; Ghavami, 2005; Terai and Minami, 2011) have also evaluated the behavior of bamboo-reinforced concrete; it

was yet suggested that bamboo has the most potential to be used as a viable replacement for steel as reinforcement in structural members.

Also, bamboo fiber has been tested on how its inclusion in concrete affects the strength characteristics of concrete (Awoyera *et al.*, 2015; Ramaswamy *et al.*, 1983). Reports from these studies indicated that bamboo fiber has no significant effect on the strength of concrete when compared with the conventional concrete.

However, it is important to ensure that bamboo does not absorb mixing water when used in concrete. At the same time, bamboo must not swell or cause any form of crack in the concrete. Therefore bamboo must be subjected to some treatment processes before being used for construction. Such treatments are mostly done to ensure that the bamboo is prevented from attacks from insects, or even deterioration. As a result, a lot of techniques have been developed to ensure that construction work done with bamboo will last for any extended period of time. Such treatments include using a solution composed of borax and boric acid, which can effectively protect bamboo against attack. There is another option of boiling the bamboo that is to be used for construction, so that starches are removed from it, because starches can attract insects to bamboo, which can cause subsequent deterioration (Fig. 11).

The mechanical properties of bamboo are presented in [Table 1](#). However, the mechanical properties of bamboo are mostly influenced by factors, such as harvesting age, species, climatic and soil conditions, moisture content, presence or absence of nodes, and location of the sample with respect to the length of the culm ([Asif, 2009](#); [Correal, 2016](#)).

Table 1 Mechanical properties of bamboo

S/N	Mechanical properties	Correal (2016)	Amada et al. (1997)	Janssen (2000)	Sá Ribeiro et al. (2017)
1	Specific gravity	0.64–0.79			
2	Compressive strength (N/mm ²)	64–75		0.094 times its density	
3	Bending strength (N/mm ²)	88–137		0.14 times its density	88
4	Shear stress (N/mm ²)			2.2	
5	Tensile strength (N/mm ²)	127–156	140–230		
6	Elastic modulus (GPa)	9.8–21.5	2		9.6

**Fig. 12** Schematic bamboo recycling process.

Recycling of Bamboo

Over the years, bamboo has been recognized as a potentially sustainable alternative to conventional materials. This is because bamboo is a rapidly growing plant, which has a rapid renewability, material strength, and most importantly, a variety of species across the globe.

Bamboo can be recycled for different uses. Activated carbon can be produced from bamboo for heavy metal removal from water or wastewater. Activated carbon otherwise known as activated coal or activated charcoal is a form of carbon that has been processed to make it extremely porous, thereby having a wider surface area that is suitable for adsorption or chemical reaction (Okada et al., 2003). Carbon has been produced from bamboo plants, which have attained a 5-year maturity period, through a process of pyrolysis. It has been suggested by Lobovikov et al. (2012) that increasing the stands of bamboo culms could serve as a means of biomass carbon sinks in some regions. A schematic recycling process of bamboo is shown in Fig. 12.

Bamboo has the capacity to purify water, owing to its extraordinary microstructure. It can also be used in many applications, from very traditional handicraft (such as baskets) to products that are completely industrialized (van der Lugt et al., 2006). Recycled bamboo is also used in furniture production.

Cao et al. (2016) developed a new combination of corncob carbon source and bamboo charcoal filter for effective nitrogen removal. From the study, bamboo charcoal served as an ideal filter material for denitrification, and it also played a role in the storage and supply of the organic matter. Similarly, lignin from bamboo shoot shells is an activator and novel immobilizing support for α -amylase (Gong et al., 2017), which is an indication that the addition of bamboo sawdust has a synergetic effect on metal immobilization in sewage sludge during copyrolysis.

Disposable bamboo chopsticks are very useful in the development of a novel type of self-supported binder-free carbon fibers/MnO₂ composite electrode. According to Wen et al. (2017), the application of bamboo for a well-designed nanostructured carbon fiber/MnO₂ composite proved suitable in the development of a sustainable and environmentally friendly energy storage device.

Apart from the use of bamboo for construction purposes, this article has also shown that bamboo can be recycled for other numerous applications, such as food production and water treatment.

Environmental Impacts of Bamboo

Bamboo in itself is mostly regarded as an environmentally friendly material. Considering the fact that it has a naturally waxy surface, which normally does not require painting, this even makes the environment safe from any health hazard that could arise from toxic substances that are present in paints. Also, there is a significant reduction in pollution with bamboo cultivation, because the plants absorb up to 35% carbon dioxide from the atmosphere – more than any other plant – and release more oxygen.

Before bamboo is used, it can be smoked in its own resin, which makes its surface stiff enough to resist the penetration of insects; this normally will protect it from insect infestation. Bamboo is one of the plants than can be grown in a variety of climates,

and as such its sustainability is also ensured. The process of cultivating bamboo is environmentally friendly, because it does not require the use of pesticides and other harmful chemicals, normally used to grow some other plants.

Furthermore, the roots in bamboo, like in some other plants, help to control soil erosion as they create a water barrier. As a result, some developing countries use bamboo to protect their crops and villages from serious climatic problems (Ataur Rahman and Rahman, 2015). According to Atanda (2015) bamboo is known to have the ability to consume a high amount of nitrogen, and this subsequently could aid drastic reduction in water pollution.

This suggests that bamboo can be grown alongside industrial areas, where there is usually a persistent pollution of water bodies due to effluent ejections. Thus it will help to convert the wastewater into nutrients normally required for its own growth. In the same vein, bamboo also has the capability to desalinate sea water.

On the other hand, studies (Joseph and Retsiakova-McNally, 2010; Suhaily *et al.*, 2013) have shown that of all the building materials that are used in construction, bamboo is the least hazardous in terms of waste, because it can easily be recycled and at the same time, it is not associated with any disposal problems.

However, despite the huge benefits accruing from bamboo trees, in some settings bamboo may have negative environmental impacts that offset the positive benefits (Yuen *et al.*, 2017). It has been accompanied with so much environmental impact. This has equally created serious detrimental effects on local ecosystems, which have been of much concern to scientific and environmental observers. Hence, there is reduction in the biodiversity of the ecosystem as well as species in bamboo forests. Most ecosystems encounter a decrease in their ability to withstand external threats, such as harsh weather conditions, attacks from diseases and pests, as well as a decrease in their ability to offer some vital supports like nutrient cycling and erosion control, which in turn affects the productivity of bamboo forests. Bamboo plantation not only brings about loss in biodiversity but also soil erosion, which in the long run leads to eutrophication at downstream as well as surface water pollution. Some environmental impacts arising from management of bamboo stands and bamboo stem harvesting as well as recycling of the product include effects on nutrient supply to ecosystem and contamination. Many species of bamboo generate natural herbicides that retard the growth of other species of plant in the underlying layer of bamboo shrubs and thereby affect the ecosystem. As a result, forages for wildlife are depleted, which in turn affects the growth of wildlife.

Sustainability of Bamboo

Being a grass, it is almost impossible to kill an entire bamboo plant by harvesting of a single culm. This is because the culms continue to grow from the underground rhizome system through vegetative reproduction (Richard, 2013). This feature makes bamboo more unique than timber, which can easily be eliminated. According to Janssen (2000), bamboo rarely flowers over its lifetime, and therefore its natural propagation takes time. Meanwhile, the vegetative reproduction is also used to expand a plantation through both horizontal and vertical cuttings.

Bamboo's sustainability may be ensured through a number of methods, such as layering, macroproliferation, and tissue cutting; all these are sustainable methods to ascertain the propagation of bamboo. For instance, during the cutting process, the typical vertical cuttings are from 2 to 3 internodes in length, which are planted in the ground much like a tree sprout. The rhizomes will first begin to grow downward from the buried bottom node, and later sprouts grow from the top nodes (Richard, 2013). While the horizontal cuttings involve burying a certain length of a green bamboo culm and trimming off the branches horizontally in the ground. Hence, the new sprouts and rhizomes will then start to grow at their nodes where branches have been cut off. A good practice is to obtain cutting material from various sources in order to reduce the impact of expansive blooming and die-off of the bamboo stock (Janssen, 2000).

It is important to note that the largest stock of bamboo in the world is mostly found in the natural forests (Janssen, 2000). Although, there are also privately owned homesteads, which are usually only for private use, with little or no material being sold. The homestead mode usually turns out to be less profitable, except if the owners would like to sell the bamboo in the market. However, in the major bamboo plantations that are owned by companies and cooperatives, the bamboo product is often sold for use in the pulp and paper manufacturing industries. Meanwhile, a huge amount of bamboo is usually required by the companies in order to ensure their continuous production.

Therefore a more sustainable measure for bamboo lies in creating more local bamboo plantation cooperatives. The yield of bamboo can be improved through the use of chemical fertilization (Liese, 1987), of which bamboo yields can increase by more than 50%, and a sustained plantation can yield an estimated amount of 5–12 t of air-dried material per hectare.

Similarly, Janssen (2000), in his estimate, reported that a well-managed plantation could yield as much as 20–30 t of the air-dried bamboo per hectare per year. Therefore bamboo is notably a renewable material, and bamboo forests could be grown in just a few years.

Summary and Conclusions

This article has briefly reviewed the sustainability and recycling of bamboo for engineering applications. The properties that are uniquely behind the choice of bamboo for some sensitive construction applications were explored. A wide range of application of bamboo for construction works were listed; these include making scaffolding for medium to tall buildings, construction of bridges and, on some occasions, for roofing applications. This study has shown that bamboo is a sustainable material, that it is one of the fastest growing plants in the world, and besides, it can be planted using various chemicals or other agricultural plant growth enhancement. In addition, another good attribute associated with bamboo is its appreciable economic importance. Private farmers and foresters are able to generate resources from bamboo plantations.

The typical bamboo elements that are mostly used include canes, halved canes, laths, beading, bamboo boards, and rope ties. So, the sustenance of bamboo for construction application offers benefits, such as prefabrication, simple assembly, simple replacement of structural parts, and moreover, the bamboo elements could easily be dismantled and reused for another application.

Sustainable Biodiesel Production

Syed H Shah, Hazara University, Mansehra, Pakistan

© 2020 Elsevier Inc. All rights reserved.

Introduction

The increased growth rate of human population and advancements in the sciences and technology has resulted the enhanced energy demands, which is expected to increase by 50% or more than it by the year 2030. The fossil fuels cannot fulfill the current energy demands, which are already expected to be 105 times faster than nature available resources. Moreover, the use of petro-fuels is damaging the environment through greenhouse gas emissions and the consequential global warming. Therefore, the search for 'clean' energy has become one of most overwhelming challenges (Shuba and Kifle, 2018; Shah *et al.*, 2018). In current era enormous global carbon dioxide (CO₂) emissions from organic fuels sectors i.e., petroleum fuels, along with greenhouse gases has resulted environmental degradation and accelerated the climate changes. Transport sector is one of the potential contributors which is uplifting the atmospheric CO₂ levels on every second on the planet earth and its share is about 20% among other sources. It is estimated that by the year 2050 over 2 billion vehicles will be contributing towards global warming and climate change (Rawat *et al.*, 2013b). Biofuels are the organic substances that contain energy from the last carbon fixation. Biofuels are derived in the form of starch, animal fats, vegetable oils, remaining biomass and algal biomass. They are biodegradable, nontoxic and robust. Biofuels are classified into first, second and third generation biofuels based on their feedstocks used and their current of future availability (Kumar *et al.*, 2018). This can bring environmental benefits because it reduces carbon dioxide, hydrocarbons and particulate emissions, reduces SO_x, and also reduces inefficient greenhouse gases. The burning of biofuels results less toxic gases emissions and reduces the carbon load in the atmosphere, as a part of carbon cycle (Jiaqiang *et al.*, 2017).

Unfortunately, current biofuel predictions are based on raw materials and are also suitable for the production of food and resources in traditional agriculture systems. Alternatives to petro-diesel i.e., biodiesel fuel include the use of land for food production and fiscal incentives to reduce food production (Jiaqiang *et al.*, 2017). To this end, in recent years, microalgae have caused the world's attention to valued natural products, their aptitude to reduce the amount of wastewater and their potential as energy crops (Satyanarayana *et al.*, 2011). Algae based fuels (biodiesel or biogas) are biofuels derived from algae. Algae is a suitable solution for the production of biofuels in renewable energy sources because of its very high potential (e.g., low input and enhanced performance) (Shuba and Kifle, 2018). Therefore, this potential can entirely substitute the fuel used to transportation oil without the need for undeniable discussion of "food versus fuel". Today, microalgae biofuels are attracting attention due to increasing interest in fossil fuels, energy security, greenhouse gas emissions and other biofuels. To commercialize microalgae cultivation and biofuels production, it is constantly being worked out by combining accumulated knowledge, legislative measures and past market demands knowledge (Stavrakas *et al.*, 2018). Therefore, the purpose of this dialogue is to summarize previous tests and results, discuss future commitments and issues in the biofuel industry, and demonstrate the differences. However, biodiesel is saturated in all soils, but it is not toxic. Biodiesel does not provide a carbon dioxide or sulfur exhausts compared to petro-diesel fuel and typically provides low pollution. These factors play an important role in the acceptability of biodiesel, which is a more serious environmental problem (Hasan and Rahman, 2017).

The first generation of biofuels have been used in transport and industrial sector around for more than a century. Biodiesel is presently produced from seed oil in the United States of America (USA). Commercially available sources of biodiesel include animal fat, rapeseed oil, corn oil, palm oil, edible oil and jatropha oil. However, the use of vegetable oils for fuel production is controversial and cannot be fully utilized to meet fuel needs in specific regions, which may have major impacts over food security and the resources like farmland and water are needed. About 1% of the world's cultivated land is used for first-generation biofuels. Only this fuel can meet 1% of the world's demand. Biodiesel production studies from the alternative sources of biodiesel from microalgae are the most suitable alternatives for petroleum and diesel fuels (Naik *et al.*, 2010).

Feed Stocks for Biodiesel Production

In 2006, world biodiesel production was estimated at 580 billion liters. Different countries have different potential for biodiesel production i.e., Germany has 48%, European countries have 30%, USA has 15%, and other countries like Brazil, China and India have 7% of this share. According to estimates for 2007, the 7% of the world's vegetable oil production was comprised by the EU. In 2006, the world's vegetable oil production was about 6000 tons. Brazil, the PR-China, Pakistan, India, Indonesia, Nigeria, the Philippines, Thailand, the United States and Uzbekistan are the main participating countries, with approximately 115 million tons. It accounts for 80% of the total output (Shah *et al.*, 2018).

Around for more than a century the first generation of biofuels have been used in energy sector. Currently, in the United States, biodiesel is formed from the oil of soybeans. Commercially, animal fat, rapeseed oil, corn oil, palm oil, jatropha oil and vegetable oil are the available sources of biodiesel (Qin *et al.*, 2012). In 2006, world biodiesel production was estimated at \$580 billion. Participation in global biofuel production and biofuel production varies from country to country. The United States and Brazil are the largest manufacturers. In the same year, 8 million tons of fat were produced. It is the most important food item used among meals. Biofuel production has a long history. In recent years, the performance of biofuels produced from various

Fig. 1 Categorization of different feedstocks for biofuels production.

raw materials has been studied. For biodiesel production, the feedstocks are divided into first generation (G-1), second generation (G-2) and third generation (G-3). In the following sections the details of these feedstocks have been studied (Shah *et al.*, 2018). The categorization of different feedstocks for biofuels production has been summarized in Fig. 1.

First Generation Feed Stocks

The first generation of biofuel feedstocks are mainly oilseeds and food crops. Beans, rapeseed, sunflower oil, palm oil and other products are mainly used in biofuel production. The first generation of raw materials consisting of vegetable oil and animal fat is based on a bio-polymer component and is mainly composed of triglyceride, diglyceride and a small amount of monoglyceride. Therefore, the first generation of raw materials is included. Since biodiesel can be obtained by simply extruding oil-containing biomass, it can be easily manufactured from previous generations of raw materials. Energy production is technically limited, but can be increased by increasing the availability of food based feedstocks. Vegetable oils contain long chain molecules with several alkyl branches and higher molecular weights. The relative molecular weight of vegetable oil varies between 850 a.m.u. to 995 a.m.u., and therefore it is much higher than diesel (average is 168 a.m.u.) (Shah *et al.*, 2016, 2018). To improve national energy security, first-generation biofuels can provide several advantages associated with carbon sequestration. G-1 biofuels can be classified according to their ability to mix with fuel oil can be burned directly from the engine. It can be installed through existing infrastructure or using alternative transportation technologies such as Flexible Fuel Vehicle or alternative fuel transport vehicles (FFV) and liquefied or compressed natural gas (LNG or CNG).

Second Generation Feed Stocks

Second-generation biofuel feedstocks include intact plant tissues such as energy crops, agricultural waste and residual wood waste. Examples of second-generation secondary sources such as *Jatropha*, *Madhuca longifolia*, tobacco seeds, jojoba oil, salmon oil, and marine mango are potential sources of the feedstocks. Waste oil, restaurant fat, animal fat, fat and pig lard are the raw materials for second-generation biofuels. In recent years, the issue of large-scale production of non-edible oilseed biodiesel has also been studied. The second generation of raw materials is more effective and environmentally friendly as compared with the first generation of raw materials. Methyl esters of animal-based fats have several advantages over primary feedstocks, such as non-corrosiveness properties, higher octane numbers, purity and continuity. Thereover they reduce and eliminate competition or crises between food and feed (Shah *et al.*, 2018). A small land area is required for their plantations and can be grown using mixed crops. Oil bearing seeds can be grown on non-agricultural land that is not suitable for the production of food crops and irrigation with wastewater side by side. Nonedible oil is not suitable as a human food item because it contains a small amount of toxic substances. The problem with G-2 feedstocks are the lack of effective technology for the commercial development of waste to biofuels production. In addition, most animal fats contain high levels of saturated fatty acids, making transesterification difficult. Therefore, because of the relatively low yield of biodiesel at low temperatures, it is not possible to completely replace current transportation fuels. Biodiesel from animal's resources using infected animals can also cause bio-protection problems. Forest biodiversity is greatly affected by the widespread cutting of trees for wood and forest residues, removing and decreasing nutrients from the soil and causing wastewater drainage. This may affect the supply of water. If the biomass resources are excepted from the

Table 1 Advantages and disadvantages of G-1, G-2 and G-3 feed stocks for biodiesel production

<i>Feed stock for Biodiesel</i>	<i>Advantages of feed stocks</i>	<i>Disadvantages of feed stocks</i>	<i>References</i>
G-1 Corn oil, Vegetable oils, sunflower oil etc.	● Economic and social security ● Environmentally friendly	● First-generation biofuels are generally edible oils ● They have limited feed stocks, i.e., possess food vs. fuel crises ● Generally, they are blended with petro-diesel, i.e., B5, B10 etc.	(Naik <i>et al.</i> , 2010; Vanthoor-Koopmans <i>et al.</i> , 2013; Ziolkowska, 2014)
G-2 Aquatic biomass, grass, agriculture and forest remains, Waste Vegetable Oil, water hyacinth and Jatropa	● Environmentally friendly ● Do not compete with food ● Less conversion cost ● Perennial plants ● Fast growing and can frequently be harvested ● Low needs for fertilizer ● Marginal land could be used ● Biomass could directly be used	● For biodiesel production grasses are not appropriate ● Require extensive processing ● Several years are needed for harvesting to obtain biomass ● Early investment in culture is considerable ● Since the seeds are weak competitors with weeds although they can be cultivated on borderline land ● They are cultivated in moist soils and do not grow fit in arid environments ● If biodiesel is not properly refined, then waste vegetable oil can reduce the engine life	(Naik <i>et al.</i> , 2010; Hou <i>et al.</i> , 2011; Ziolkowska, 2014)
G-3 (Chen <i>et al.</i> , 2011) Algal biomass, (Microalgae and macroalgae)	● Microalgae can be grown on diverse types of carbon sources ● The total carbon emissions can potentially be reduced ● Scale up technologies are easy ● In closed photobioreactors they have low water use and many strain can be utilized ● Organic solvents are used to extract lipids from microalgal biomass (dry and wet).	● A minor limitation is that microalgal biodiesel is less stable and could be vulnerable to biodegradation ● The presence of unsaturated fatty acids among extracted lipids can have more volatile nature than saturated lipids ● At elevated temperatures they are less stable and more vulnerable to degradation ● The cost of microalgal biofuel is moderately higher than other feedstocks ● In case of different photobioreactors the microalgal cultivation rates and biomass productivity are variable ● The technology appears to be costly for commercial scale	(Stephens <i>et al.</i> , 2010; Brennan and Owende, 2010; Oncel, 2013)

likelihood of bioenergy, the energy potential of second generation biofuels will be greatly reduced (Naik *et al.*, 2010). The advantages and disadvantages of different feedstocks for biodiesel production are summarized in **Table 1**.

Third Generation Feed Stocks

Microorganisms are potential feedstocks as third-generation biodiesel feedstocks (G-3) for biodiesel production. A variety of microorganisms can be used for this need. Microalgae are considered as the most promising opportunity for biodiesel production. Algae are roughly divided into two groups according to its size and shape i.e., large algae (macroalgae) and microalgae. For example, large seaweeds with more plants resembling roots, stems and leaves can produce more biomass. In contrast, microalgae are common in freshwater, wastewater and seawater (Shuba and Kifle, 2018). Microalgae are photosynthetic organisms, also found as mixotrophic and heterotrophic microorganisms. Because their lifestyles are aquatic, colonial or free, and due to photosynthesis properties, these are suitable for the production of specific chemicals as feedstocks for the synthesis of biofuels products in industrial processes. Autotrophic algae use inorganic carbon sources, heterotrophic organisms use organic carbon sources. The production of biodiesel from these two microalgae (autotrophic and heterotrophic) is different. They require less surface area for their growth and have high oil content as a part of their biomass. Microalgae do not require large area for their cultivation as required by food crops and similar plants (Shah *et al.*, 2016, 2018).

Microalgae as Emerging Feed Stock for Biodiesel Production

Microalgae are by far the only organisms known to show photosynthesis and production of oxygen. Microalgae grow in natural and artificial environments as well. Microalgae are simple microorganisms having the growth requirements that need light, carbon

dioxide and other inorganic nutrients, and have the ability to grow in a variety of environments. Microalgae also can reduce air pollution by reducing atmospheric carbon dioxide levels. They use carbon dioxide which is a greenhouse gas in the atmosphere. Approximately it takes 1.8 kilograms of carbon dioxide to produce 1 kilogram of algal biomass. Some microalgae contain more than 80% of dry biomass. According to Oilgae report (2010), some microalgae have about 15%–40% (dry weight). However, the palm oil content is about 50%. Beside this the coconut oil content is 60% and sunflower oil content 55%. In actual fact, microalgae possess highest yield compared with many other vegetable oils. Palm trees, coconuts, castor and sunflowers produce 5950, 2689, and 1413, and 552 L respectively of oil per hectare per year.

Microalgae can be used to get a variety of biofuels. They can produce methane (CH_4), bioethanol, hydrogen, and biodiesel through a variety of processes. Microalgal biofuels could be used without changing existing fuel engines structures. The properties of petro oil-based diesel fuel such as cold filter point, calorific value, density, flash point, viscosity and condensation point are like those of biodiesel derived from microalgae. Mostly the parameters meet the requirements of the American Society for the Testing and Materials (ASTM). Microalgal biodiesel also meets the requirements of the international automotive biodiesel standard. A comparison of petro-oils and bio-based oils obtained by rapid pyrolysis of wood and microalgae shows that microalgae have a higher calorific value, lower density and lower viscosity than bio-oil (derived from wood). Due to its high quality, microalgae oil is better than bio-oil from lignocellulosic oil. The presence of high content of polyunsaturated fatty acids present in the microalgal oil leads to oxidation during storage and limits the use of oils for vegetable oils (Shuba and Kifle, 2018).

Microalgae primarily multiply their cells by the uptake of nitrogen (N_2) and phosphorus (P) present in the wastewater. Microalgae tend to remove inorganic nutrients from the wastewater and produce more oil containing biomass. Of course, this process is very expensive at the industrial level. Finally, microalgal biomass can be collected for lipid extraction and biodiesel production. The possibilities of cyanobacteria and microalgae-based biofuels are economic and ecological. They can reduce the dependence on fossil fuels as an energy basis. Many eukaryotic microalgal strains can synthesis and store a large quantity of energy enriched compounds, i.e., starch and triacylglycerol (TAG), which can be used to make biofuels, including biodiesel and bioethanol. The combination of cultivation and wastewater treatment can result a large amount of biodiesel amounts to reduce the impacts of energy crisis (Mubarak *et al.*, 2015).

There are few fresh water microalgal species that are investigated for wastewater treatment i.e., *Scenedesmus* sp. and *Chlorella* sp. They can potentially remove excess of nitrogen and phosphorus from wastewater. Microalgae have many advantages over other feed stocks, in the removal of nitrogen and phosphorus. There are many advantages of microalgae, i.e., *Scenedesmus* sp. and *Chlorella* sp. are used to treat wastewater. They remove excess of nitrogen and phosphorus from the wastewater. Microalga have many advantages over other feedstocks, beside removing nitrogen and phosphorus from the wastewater (Rawat *et al.*, 2013a; Shuba and Kifle, 2018). They have the following benefits:

- Increase the oxygen concentration in the water i.e., dissolved oxygen.
- Solar photobioreactors make the downstream process efficient for algae biomass production
- Reduce carbon dioxide from the atmosphere at the same time.
- Additional supply of organic carbon is not needed as compared with biological nitrification and denitrification.

Compared to diesel, biodiesel is like ordinary diesel. Therefore, it can be used to directly reduce carbon monoxide (CO) or sulfur oxides (SOx) emissions in diesel engines. In addition, microalgae have high photosynthetic capacity and can efficiently produce high quality of oil. The lipid productivity of microalgae dry biomass is an approximate unit. It is 15–300 times more than a traditional crop. Therefore, microalgae is considered a promising alternative to petroleum fuels (Jiaqiang *et al.*, 2017).

Downstream Processing for Microalgal Biodiesel Production

Light and nutrients are the essential components of microalgal growth. Microalgae consume nutrients in the presence of light and convert them into organic compounds. Microalgal cultivation is affected by aeration, carbon source, light, nutrients composition, temperature, pH and photoperiod. A number of culture media have been introduced for microalgal cultivation. Nutrients pose high cost on microalgal cultivation. Alternatively, wastewater can be used as a growth medium for microalgae cultivation and growth (Halim *et al.*, 2012).

Light and nutrition (C:N:P:K) are the important elements in the growth of microalgae. Microalgae slightly utilize the nutrients to form organic compounds. By aeration the culture of microalgae are affected, and the other impacting parameters are light intensity, carbon source, nutrients, pH, temperature and photoperiod. Many experiments have been carried out for the culturing variations for microalgae and biomass production. Nutrients can cause significant costs for the growth of microalgae. And wastewater can also be used as a means of growing and reproducing microalgae for biodiesel production (Demirbas, 2011; Liang *et al.*, 2009).

The cultures of microalgae can use wastewater as a source of nutrients, and its use can achieve two goals, i.e., removing pollutants and producing biofuels. Seawater is one of the economic methods among others for growing microalgae. In sea water the essential nutrients for growth are present and for mass cultivation the nutrients concentration may be varied. There are more than 70 elements in seawater, but 6 elements account for 99% or more of completely dissolved salts. These salts are present in ionic form in their aqueous solution, i.e., Na^+ , K^+ , Mg^{2+} , Ca^{2+} , Cl^- , CO_3^{2-} and SO_4^{2-} (Ahmad *et al.*, 2012). Biodiesel production from algae biomass by adopting downstream processing has been summarized in Fig. 2.

Fig. 2 Biodiesel production from algae biomass by adopting downstream processing.

Microalgal Cultivation

Apart from nutrients supplement, microalgae cultivation system also plays an important role to determine the success of the industry. An effective culture system should consist of the following criteria: (1) effective illumination area, (2) optimal gas–liquid transfer, (3) easy to operate, (4) low contamination level, (5) low capital and production cost and (6) minimal land area requirement. Apparently, only raceway pond is implemented in commercial scale for microalgae cultivation to produce high-value nutritious products for animal feed. The system consists of a paddle wheel to avoid microalgae biomass sedimentation and CO_2 is sparged at the bottom of the raceway as carbon source. In addition to the nutrients requirements for microalgal growth, the cultivation systems also play an important role in the success of the industry. Effective planting systems are (1) effective lighting areas, (2) optimal transport of gases and liquids, (3) simple use, (4) less pollution, and (5) cost effectiveness. It is evident that at commercial scale microalgal biomass production can produce high value oil for the biodiesel production. The raceway ponds for the cultivation consists of paddle wheels and homogenizers, that prevents microalgal biomass from precipitating and introduces CO_2 as a carbon source during the growth phase (Rawat *et al.*, 2013b).

There are many types of closed photobioreactor structures, such as gas lifts, flat plates, bubble column and vertical column. The key benefit of cultivating microalgae in a closed photobioreactor is that the single strain cultures are maintained at the optimal conditions without being contaminated and can result the improved consistency of biomass production and lipid accumulation. Therefore, closed photobioreactors are of great interest to researchers to further improve commercial scale operating conditions. In addition, it can further enhance the mass transfer of carbon dioxide to the medium and increase the growth of microalgae cells. Alternatively, the deflector system can be easily installed on the current set of tracks without any significant changes. However, the efficiency of photobioreactors could be evaluated on the basis of lattice cell deflection systems, fluid dynamics, mass transfer, efficiency of CO_2 transfer, turbulence effects of on microalgal growth, energy balance and scalability (Demirbas, 2011; Shah *et al.*, 2016).

Microalgal Biomass Harvesting

When the microalgal culture reaches at the stationary phase, the next stage is to separate or harvest the fresh biomass from the nutrients solution and to get seed for the next cultures. However, the microalgae are microorganisms (usually 1–20 microns) and are suspended in the liquid, so it is difficult for the skilled person to recover the microalgae. Currently, there are several ways for microalgal harvesting, i.e., sedimentation, filtration, floatation, centrifugation and flocculation (Pragya *et al.*, 2013).

Recent research on LCA has emphasized the harvesting and drying of microalgal biomass to provide considerable energy for biodiesel production from microalgae. In this case, the results indicate that a large number of collection methods can play an important role in reducing the energy demands during concentration of the microalgae suspension. Therefore, the energy consumption during the extraction and drying of microalgal biomass cannot be exempted. In fact, microalgae may have a significant negative impact on the overall energy balance of biofuel production (Taher *et al.*, 2014). Centrifugation and filtration have not been a viable method for harvesting microalgae on an industrial scale. Alternatively, flocculation provides a relatively low energy form for the concentration of microalgae. In fact, since microalgal cells are always negatively charged, they stay in the liquid for a long time and repel without mixing. The negative charge around the cells with fine elements is neutralized by introducing a coagulant in the medium. Simultaneously, the coagulant can be added to the agglomerated bridge between the aggregate and the neutralizing cells, and becomes clustered and settled flock due to gravity (Anthony *et al.*, 2013). Another probable way for microalgal harvesting is by immobilization technologies, as microalgae are continuously deposited in the matrix i.e., by the captured matrix. When the microalgae reached the fixed bed and the mixture was completed, the microalgae biomass immediately settled to the bottom of the medium. Therefore, relatively large

micronutrients can be easily separated from water by a simple filtration process (e.g., screening) that is not so much energy intensive (Pragya *et al.*, 2013).

Biomass Drying and Lipids Extraction

Unlike energy crops on the ground, biofuel production requires large amounts of dry particulate biomass, because the presence of water can restrict the subsequent downstream processes i.e., lipid extraction and transesterification for biodiesel production. However, this issue is not a big issue. This is because after the harvesting, solar drying is considered to be the best way to dry wet microalgal biomass. However, due to limited sunlight, it is important to have research on the areas where the day light duration is less throughout the year (Shah *et al.*, 2018).

In this case, in order to ensure optimal biomass production, heat must be generated from fossil fuels to continuously dry the microalgal biomass in the cultural cycle. However, recent LCA studies indicate that if natural gas is used to dry biomass, it will consume about 69% of the total energy input and produce a negative energy balance when microalgae produce biofuels. Alternatively, the high dependence of dry microalgal biomass on fossil fuels significantly impairs the commercial viability of microalgal fuels and new technologies or methods, such as the efficient development of dryers. Therefore, it confirms that the biofuel sector of microalgae is sustainable. Other strategies are also used, such as in situ partial transesterification and partial or non-drying treatment of microalgal biofuels by hot water liquefaction (hydrothermal) (Patil *et al.*, 2011).

Once the microalgal biomass is collected and dried, the next step is to extract the lipid. The energy required to extract lipids from dry particulate dry biomass accounts for a relatively small percentage (about 5%–10%) of the total energy of the biofuel-containing algae, but this method is still very significant. In the case of low lipid microalgae, loss of lipids during extraction may have a significant impact on the production of biodiesel, therefore, effective lipid extraction is necessary. Unlike terrestrial energy crops, the extraction of lipids from microalgal biomass is relatively difficult due to the presence of thick-walled cell walls that prevent lipid release. Therefore, the mechanical pressure to effectively release oil from terrestrial energy crops is generally not applicable to microalgal biomass. The subsequent sections describe two methods of lipid extraction: (1) solvent extraction for dried microalgal biomass and (2) lipids extraction from wet microalgal biomass through supercritical fluid extraction (Park *et al.*, 2015).

The most common method of extracting lipids from dried microalgal biomass is by chemical solvent extraction i.e., Bligh and Dyer methods. In fact, chemical solvents have high lipid selectivity and solubility, and even the solvents can diffuse and extract lipids on the cell walls of microalgae. In this method the organic solvents such as ethanol, methanol, n-hexane, and methanol-chloroform mixtures (2:1 v/v) can effectively extract lipids from microalgae (Mubarak *et al.*, 2016). For chemical solvent extraction, diffusion is always a limiting factor in the overall lipids extraction mechanism. But, it becomes more difficult in case of microalgae because the rigid cell wall prevents the solvent from diffusing into the cell content to extract lipids. Therefore, in order to increase the diffusion efficiency of the solvent, beads beating method can accelerate the lipid extraction rate from microalgal biomass. There are several pretreatment methods to disrupt the cell walls of microalgae, such as bead-beater, autoclaves, ultrasound, and osmotic shock and microwave (Iqbal and Theegala, 2013; Araujo *et al.*, 2013).

In recent years, the introduction of supercritical fluid extraction technology has made a new, dynamic era of lipids recovery and biodiesel production from oleaginous biomass. The fundamental principle of the method is to reach a specific stage (supercritical) other than the critical point of the liquid, and the meniscus of the separated liquid phase separated by evaporation and leaving only the homogeneous phase. In the supercritical phase, thermal and physical properties such as diffusion coefficient, viscosity, fluid density and dielectric constant vary greatly with temperature and pressure (Mubarak *et al.*, 2015).

Thus, changes in thermophysical properties turn the liquid into a super solvent and increase the efficiency of the extraction and reaction. Currently, supercritical fluids such as ethylene, ethane, ethanol, carbon dioxide, methanol, toluene, benzene and water are being studied. Among them, supercritical extraction by carbon dioxide generally employed on the products recovery i.e., of drugs or health-related products from microalgae. Recently, in order to produce biodiesel, it has been studied to extract lipids from microalgae using supercritical carbon dioxide extraction method (Mouahid *et al.*, 2013).

Biodiesel Synthesis Though Transesterification

Lipids extracted from microalgal biomass can be converted to biodiesel. In the following several possible methods for obtaining biodiesel from microalgal lipids using homogeneous and heterogeneous catalysts for the transesterification are discussed. The common method used for preparing biodiesel is the transesterification of a triglyceride (e.g., vegetable oil) with a short chain alcohol (e.g., ethanol or methanol) by adding a suitable catalyst in the reaction medium. Common base catalyst such as NaOH and KOH are used for the transesterification of triglycerides (Baskar and Aiswarya, 2016).

The inclusion of high free fatty acid (FFA) content (greater than 0.5% w/w) in microalgal lipids prevents the use of homogeneous basic catalysts in the transesterification reaction. In fact, free fatty acids react with the main catalyst to form soap, reduce the production of biodiesel, and complicate the separation of glycerol (by-product) and biodiesel (Jin *et al.*, 2014; Zhang *et al.*, 2015). Acid catalysts such as sulfuric acid (H_2SO_4) are more suitable because the catalyst is not sensitive to the FFA level of the oil. Thus, esterification (the conversion of FFA to alkyl ether) and transesterification proceed simultaneously. Based on modern

technology, a two-step process involving acidic and basic catalysts is the best alternative to converting microalgae-based biodiesel (Eq. (1)) (Shah *et al.*, 2016, 2018)

The microalgae lipids are pretreated with acid to reduce FFA levels prior to transesterification with a base. These two stages of process are successfully applied to high FFA biodiesel feedstocks (such as jatropha oil and vegetable oils) and can be simply extended to industrial applications based on scale up techniques. However, the main disadvantage of these two processes is the additional cost of neutralizing the acid catalyst and biodiesel using an additional basic catalyst while transesterification process (Park *et al.*, 2015). To date, in the literature, the conversion process of microalgae biodiesel with alkaline catalysts or homogeneous acids is still very limited. Heterogeneous catalysts (acids or bases) are also widely used in transesterification reactions to produce biodiesel. Different homogeneous and heterogeneous catalysts can be regenerated and recycled in subsequent transesterification cycles to increase the profitability of biodiesel production (Pawera *et al.*, 2017). Further, the catalyst can easily be removed by filtration at the end of the reaction, thereby minimizing product contamination and cleaning cycle time (washing). To date, research on heterogeneous catalysts for the production of microalgae for biodiesel has been limited because it is a relatively new raw material and cannot be used. The commonly used heterogeneous base catalyst; CaO supplemented with Al₂O₃ have been studied in transesterification of oil derived from *Nannochloropsis oculata* (Mohamad *et al.*, 2017; Steriti *et al.*, 2014).

Quality and Application of Biodiesel

Microalgae are acceptable as an alternative to fossil diesel fuel and is highly dependent on compliance with applicable standards. Generally, the physical properties of finely derived biodiesel are comparable to those of diesel. The current references are the American Society for Testing and Materials (ASTM D 6751 07 b) and the European Union (EN 14214:2008). Many researchers compared the properties of biodiesel and compared ASTM standards for cetane number, viscosity, cold filters, calorific value, viscosity, density, flash point, hot spots, freezing points and few other parameters as well. Biodiesel derived from microalgae has a low plugging point temperature of $-11\text{ }^{\circ}\text{C}$, which is considerably lower than petro diesel (Ejim, 2015; Oasmaa *et al.*, 2009). The use of chemical transesterification and feedstock production of biodiesel is a simple and straightforward process by which glycerol is produced as a by-product. The biodiesel or fatty acid ester extracted after the reaction is mixed with contaminants such as alcohol and soap, and thus can be considered wet and impure. Therefore, to eliminate these contaminants, high concentrations and processes are required to ensure that biodiesel fuel quality meets the requirements of the American Society for Testing and Materials (ASTM) Standard. Biodiesel of poor quality and grade is harmful to diesel engines and may void the engine manufacturer's warranty (Mohamad *et al.*, 2017; Oasmaa *et al.*, 2009). The comparison of the properties of biodiesel standards with Petro-diesel are summarized in Table 2.

Table 2 Comparison of properties of microalgal biodiesel and petro-diesel with ASTM biodiesel standard

Properties	Biodiesel from microalgal oil	ASTM D6751 07b	Diesel fuel (EN 590:1999)	EN 14214:2008
1. Density (kg/l)	0.864	–	0.838	0.86–0.90
2. Viscosity (mm ² /s, cSt at 40 °C)	5.2	1.9–6	2.0–4.5	3.5–5
3. Flash point (°C)	115	> 93	> 55	> 101
4. Solidifying point (°C)	12	–	50 to 10	–
5. Cold filter plugging point (°C)	11	^a	^a	^a
6. Acid value (mg KOH/g)	0.374	Max 0.5	Max 0.5	–
7. Heating value (MJ/kg)	41	–	40–45	–
8. H/C ratio	1.81	–	1.81	–
9. Cetane number		47 min	51 min	51 min

Sustainability Perspectives of Biodiesel Production

Since algae biomass has the potential to accumulate lipids in cells, algae biomass produces biodiesel with a yield of more than 100 times per acre, and is therefore one of the most important alternative fuels. The chemical method for enhanced lipid extraction is promoted by supercritical fluid extraction, Soxhlet extraction and organic solvent extraction. Mechanical methods include hydrothermal extraction, ultrasonic extraction and microwave assisted extraction. Compared to diesel fuel, biodiesel can be used directly in diesel engines to reduce carbon monoxide (CO) or sulfur oxide (SOx) emissions, unlike conventional diesel fuels. In addition, microalgae have a high photosynthetic capacity and can effectively accumulate the lipids content. Microalgae have lipid productivity per unit dry biomass 15–300 times more than conventional cultivation of terrestrial crops. Therefore, microalgae are considered a promising alternative to petroleum fuels.

Biofuels and bioethanol are undeniable issues for the World Trade Organization (WTO), complicating product transactions. According to experts, some energy producers have become WTO members and have never studied energy issues. Biofuels are no longer guaranteed because they are only a small part of the world's energy supply. Biodiesel is still classified as an industrial product. However, the use of bioethanol is uncertain (Shah *et al.*, 2018; Florentino de Souza Silva *et al.*, 2014).

The WTO classified bioethanol as an agricultural product. This is due to the different materials used to produce bioethanol for bioethanol and biodiesel according to different classification methods. In addition, the use of bioethanol has many advantages, including reducing greenhouse gas emissions from automobiles and improving vehicle efficiency and economy. Biodiesel is exempted from fuel taxes in European countries such as France and Germany. Europe is a leader in biodiesel production, i.e., France, Germany and Italy being the most important countries. In Europe, Spain is a leader in bioethanol production. In addition to these countries, countries from other continents such as Brazil, North America and Southeast Asia have also introduced new policies (Ziolkowska, 2014).

Therefore, the scientists are getting more opportunities for projects scale-up and commercialization. The infrastructure development, commercialization, education and outreach programs, public awareness, monitoring, subsidies, government participation, technology transfer and adoption, evaluation and lack of appropriate policies should be the hallmark of the mentioned technologies and recommendations. As a result, researchers have more opportunities to develop and commercialize projects. Infrastructure development, marketing, education and public relations programs, public awareness, monitoring, subsidies, technology transfer, country participation, and implementation, appropriate assessment policies and lack of appropriate policies must be the characteristics of above mentioned technologies and recommendations (Pragya *et al.*, 2013).

Conclusions

Due to the drastic consequences of fossil fuels burning and greenhouse gases emissions, there is dire need to promote and utilize the renewable energy resources. Solar energy, wind energy, tidal energy, geothermal energy and bioenergy (biofuels) are the main sectors of renewable energy options. Microalgal biodiesel is a promising biofuel which has multiple benefits, i.e., CO₂ sequestration, nutrients removal from water, efficient conversion of solar energy into chemical energy and lesser emissions of toxic and greenhouse gases. Several achievements have been made for sustainable biodiesel production and scale-up technologies. Microalgae used for biodiesel production has eliminated the use of food oil and minimized the demands to large land areas for cultivating feedstock (jatropha and oil seed crops) and water demands for irrigation. Additionally, many technical sides have been upgraded during algal biomass production and biomass processing techniques to yield more oil than terrestrial crops. Still the cost effectiveness is a great challenge. But by the improvements in downstream processes i.e., cultivation, harvesting, biomass processing, lipids extraction and transesterification the microalgal biodiesel production could be scaled up and commercialized.

Introduction

Classification of Cotton

Cotton is classified in the genus *Gossypium* of the mallow family, *Malvaceae*. According to Fryxell (1992), the genus *Gossypium* consists of 4 subgenera and 50 species. Among these, *G. herbaceum*, *G. arboreum*, *G. hirsutum* and *G. barbadense* are the four cultivars widely grown. *Gossypium hirsutum*, also called New World or upland cotton, and *G. barbadense*, the source of Egyptian cotton and Sea Island cotton, supply most (98%) of the world's cotton fiber. Levant cotton (*G. herbaceum*) is native to southern Africa and the Arabian Peninsula. Asian cotton (*G. arboreum*) is native to India and was first cultivated and spread in Asia. Both *G. herbaceum* and *G. arboreum* are diploid and are known as Old World Cotton.

Cotton fiber is most often spun into yarn or thread and used to make a soft, breathable textile, which is a renewable natural resource. The use of cotton for fabric is known to date to prehistoric times. Currently, more than half of the clothes people wear are made of cotton fiber, hence the cotton plant has gained the reputation of "clothing the world".

Cotton Production in the World

Cotton has a long history of cultivation, being globally distributed across Asia, North America and Western Africa. According to data from the International Cotton Advisory Committee in 2015 (the annual report of the international organization), more than 80 countries around the world plant cotton, mostly in Asia and America. Cotton production in these two continents accounts for more than 80% of the world's total. Asia is the world's largest cotton producing continent, accounting for 70% of global production. The leading cotton producing countries are China, India, Pakistan, Uzbekistan and Turkey, which together account for half of the world's and 95% of Asian production. North America is the second largest cotton producing continent, accounting for 18% of the world's total. The major cotton producing countries are the United States and Mexico.

Growth and Development Habit

Cotton was originally a perennial plant. After long-term planting, domestication, artificial selection and cultivation, it evolved into an annual plant. Therefore, it not only follows the general growth pattern of annual crops, but also has the following characteristics:

Firstly, cotton has an indeterminate growth habit and can grow continuously under conditions of unrestrained growth.

Secondly, the plant has great plasticity. The height and vegetative growth are affected by environmental conditions and cultural practices.

Thirdly, cotton can adapt to different environmental stresses to some extent. It can survive when soil moisture (10–30 cm) is reduced to 8%–12%. At low and moderate salinity, its growth and development are almost unaffected. After 3–4 days of waterlogging, cotton could still return to normal growth.

Fourthly, the plants grow vegetative at the early stage of development, and then transit to reproductive stage until senescence and maturity. However, there is a long-term overlap between vegetative growth and reproductive growth, accounting for almost 4/5 of the whole growth period.

Fifthly, cotton has the ability to compensate for damage. It has a potential to compensate for loss of the fruiting structures. For example, cotton can sustain relatively high levels of first position square loss with negligible yield loss.

Growth Stages of Cotton

Cotton requires a relatively long season (from 180 to 200 days) with sunny and warm weather and plenty of water during growth and development. The growth stages of cotton consist of emergence, seedling, squaring, flowering, boll-setting and maturity (boll opening) stages.

With good soil moisture and warm temperature at planting, cotton usually emerges 5–7 days after planting, with a full stand establishment at about 11 days. The seedling stage usually lasts approximately six weeks, and then squares or flower buds begin to form and enter the squaring stage. The squares mature in three weeks and then blossom into creamy yellow flowers, which turn pink, then red, and finally fall off three to four days after blossoming. After the flower falls off, a tiny ovary is left on the cotton branch. This ovary ripens and enlarges into a green pod called cotton boll; the boll matures (opening) in 55 to 80 days.

Fig. 1 Cotton seedlings. (a) Pre-emerged seedlings from the soil; (b, c) seedlings at 18 days after planting.

Cotton Growth and Development

Germination and Emergence

Germination begins as the seed absorbs water through its chalaza after seeding. The water swells the dormant tissues, and cell growth and division begin to take place. The radicle emerges through the micropyle, turns downward, and grows deeper into the soil as the taproot that will supply water and nutrients throughout the whole life of the plant. The hypocotyl elongates from the radicle and forms a hook that begins to push up through the soil. Seedling emergence normally takes place 4–14 days after seeding. At the soil surface, the hypocotyl straightens and pulls the folded cotyledons out of the soil. After the cotyledons are pulled through the soil surface, they unfold and expose the epicotyl and the apical meristem. At this point, germination and emergence have been completed and the plant begins its active vegetative growth (Ritchie *et al.*, 2004) (Fig. 1).

Root Establishment

Cotton has a straight root system, which is in a net-like inverted conical shape in the soil. It consists of the main root, lateral roots, small roots, hairy roots and root hairs. The depth of the main root can be more than 2 m in the soil, and the extension of the lateral roots can reach 0.6–1 m horizontally. The establishment of the root system includes four stages: root development stage (from seed germination to squaring), root growth stage (from squaring to flowering), peak root absorption stage (from flowering to initial boll-opening) and root activity declining stage (during boll opening). The root growth stage is the key growth period of the main and lateral roots, and the number of active roots in the plough layer is greatly reduced and the ability for absorbing minerals is also significantly decreased at the root activity declining stage.

Stem and Branch Growth

Stems and branches are the skeleton of cotton plants. The main stems are gradually formed by the growth point of the stem through cell proliferation, differentiation and growth. The growth of cotton main stem is slow at the seedling stage. It grows faster at the squaring and flowering stages, and peaks at the initial flowering stage. After peak flowering, the growth of the main stem slows and stops after the boll-opening stage. The branches on a cotton plant can be classified as vegetative branches (*monopodia*) and fruiting branches (*sympodia*) (Ritchie *et al.*, 2004). The fruiting branches are generally formed in the middle and upper parts of the main stem, and the branches stretch outward horizontally, so they exhibit axis branching. The squares and bolls are directly formed on the fruiting branches. Because vegetative branches have only one meristem, they grow straight and erect, much like the main stem. Vegetative branches are produced after fruiting branches and below the node at which the first fruiting branch was developed.

Leaf Growth

Cotton leaves are heart-shaped, lobed, and coarse veined, somewhat resembling a maple leaf. After a cotton seed has sprouted (about four to five weeks after planting), two “seed” leaves provide food for the plant until additional “true” leaves appear.

As the cotton plant develops, new leaves appear and expand, increasing sunlight interception (Ritchie *et al.*, 2004). Initially the carbohydrates produced by the leaves are used to produce roots and more leaves. This production of new leaves causes the leaf area of the cotton plant to increase rapidly. Leaf photosynthesis does not remain constant as the leaf grows and develops. A cotton leaf reaches its maximum photosynthetic capacity at about 20 days of age, after which it declines.

Squaring, Flowering, and Fertilization

Cotton seedlings begin to differentiate into squares at the 2 or 3 true leaves stage. Based on the structure of floral organ, flower and square differentiation begins in an outside-in pattern. The 6 periods of the differentiation are flower primordium elongation, temporal primordium differentiation, square primordium differentiation, petal differentiation, stamen differentiation and pistil differentiation. After squaring, the primordium continues differentiation; the filaments are elongated, the ovules protrude from the pistil, the septum is formed, and the ovules are formed. The stamens form pollen mother cells 7–10 days before flowering, and form a tetrad by meiosis. The isolated single cells form pollen grains.

Flower buds protected by a fringed, leafy covering develop a few weeks after the plant starts to grow, and then bloom a few weeks later. The flower usually blooms in the morning and then withers and turns color within two to three days. The bloom falls off the plant, leaving a ripening seed pod.

Pollination must occur before the flower falls off. The entire pollination process is completed within 24–48 h after blooming. Pollen from the stamens (male part) is transferred to the stigma (female part) by insects or wind, and travels down the stigma to the ovary. It takes about 8 h for the pollen tube to reach the ovary. The ovary contains ovules, which become seeds if fertilized. The ovary swells around the seeds and develops into a boll (Fig. 2).

Boll Development

After pollination the boll begins to develop. Under optimum conditions it requires approximately 50 days for a boll to “open” after pollination. Boll development can be characterized by three phases: enlargement, filling, and maturation. The enlargement phase lasts approximately 3 weeks. During this time the fibers produced on the seed elongate and the maximum volume of the boll and seeds contained therein are attained. The filling phase begins during the fourth week after flowering. At this time, fiber elongation ceases and formation of secondary wall on the fiber begins. The filling phase continues into the sixth week after pollination. The boll maturation phase begins as the boll reaches its full size and maximum weight. During this phase, fiber and seed maturation takes place and boll dehiscence occurs. The capsule walls of the boll dry out, causing the cells adjacent to the dorsal suture to shrink unevenly. This shrinking causes the suture between the carpel walls to split, and the boll opens (Ritchie *et al.*, 2004).

Seed Development

Cotton seeds are endosperm-free seeds developed from ovules after fertilization. The development of seeds corresponds with the development of bolls. The ovules begin to expand after fertilization and reach the peak volume 20–30 days after flowering. The fertilized eggs began to divide 4–5 days after flowering. After 15–20 days, cotyledons, germs, hypocotyls and radicles are clearly visible, and the seeds acquire germination ability. At the same time, nutrients in the endosperm are gradually absorbed and utilized by the embryo, and become enveloped in a film outside the embryo, while the embryo is full of seed shell.

Fiber Development

Cotton fibers are developed from epidermal cells of ovules after fertilization. The shape, structure and formation process of fibers are closely related to their quality and economic value. Mature cotton fibers have good consistency in structure, fineness and strength, and thus have ideal spinning and dyeing properties. A mature cotton fiber can be roughly divided into base, middle and tip parts. The cross section of mature fibers is mostly elliptical or circular, consisting of many concentric circles, which can be further divided into primary wall, secondary wall and central cavity. The primary wall is the primary cell wall of fibroblasts, which

Fig. 2 Parts of a mature cotton flower.

is composed of pectin and cellulose. Externally, waxes, pectin, fat and resin form a very thin cuticle. The secondary wall is the main part of cotton fibers, almost all of which are composed of cellulose. It is a wheel-like layer. The thickness of the secondary wall is related to fiber strength. The secondary wall of mature fibers is thicker, the middle cavity is smaller, and the strength of the fibers is higher. The innermost layer of the fibers is the lumen, which is left when the cell wall stops thickening.

The morphogenesis of cotton fiber is comprised of four developmental stages: initiation, elongation, secondary wall thickening, and maturation. The formation of fiber initials is observed as balloon-like protrusions on the ovule surface at anthesis. After initiation on the day of anthesis, single-celled fibers undergo the second stage called fiber elongation. Fiber elongation occurs over a period of approximately 21 days, with accelerated growth, reaching peak levels at approximately 5 to 20 days post-anthesis (DPA). This period is critical for fiber elongation. If the plant is exposed to drought stress at this period, the fiber would not elongate sufficiently. Under normal circumstances, cells initiated within about 3 DPA can form long fibers; cells initiated from 4 to 10 DPA can only form short fibers (fuzz) (Wilkins and Arpat, 2005).

Termination of fiber elongation is accompanied by a corresponding thickening of the cell wall, which lasts for 25–35 days. At 5–10 DPA, the cell wall thickens and the middle cavity becomes smaller due to the deposit of cellulose in the centripetal layer of the primary wall (Wilkins and Arpat, 2005). The maturity starts from boll cracking to full opening, which lasts about 5 days. With the cracking of bolls and fiber-dehydration, the residual protoplasm in the cavity dries up gradually, causing the fibers to shrink into flat tubes. Due to the spiral arrangement of small fibers and changes in spiral direction, an internal stress occurs that twists the fibers.

Yield and Yield Components

Biological and Economic Yields

The biological yield of cotton refers to the total amount of dry matter that cotton absorbs and synthesizes during its lifetime after subtracting the consumption of respiration. The economic yield refers to the seed cotton yield or lint yield. Of the total dry matter of cotton, 90%–95% comes from photosynthesis, and only 5%–10% comes from the absorbed mineral nutrients. Therefore, the biological yield depends on the amount of photosynthetic products. However, whether high economic yield can be achieved also depends on the harvest index which is the ratio of economic yield (seed cotton) to biological yield.

Yield Components

Cotton yield is formed through fruiting (boll setting). The basic components of lint yield are the number of bolls per unit land area (fruiting sites and boll retention), weight per boll (cotton weight per boll seed) and lint percentage. The relationships between cotton lint yield and its components are complex (Constable, 2012). They are dependent on genetic and environmental variation and their interactions. The primary yield components that contribute to seed cotton yield are the number of bolls per unit area and boll weight. Thus the most commonly used yield component equation for cotton is the geometric model proposed by Kerr (1966):

$$\text{Seed cotton yield} = \text{bolls/unit area} * \text{average single boll weight}$$

Boll density

The number of bolls is determined by fruiting sites and fruit retention, which can be monitored during early boll development and possibly manipulated by field management to maximize yield. Different yield components contribute to lint yields at varying degrees. Increases in yield are generally associated with the number of bolls per unit ground area (Pettigrew, 1994; Wells and Meredith, 1984). The number of bolls/m² is affected by soil fertility level, soil water content and planting density.

Boll weight

The boll weight may be more genetically determined than boll density. Boll weight is the main determinant of yield when the number of bolls is the same. In addition to the genetic characteristics of the varieties, the boll weight is affected by temperature and heat accumulation. The optimum temperature for boll development is 25–30°C. When the active accumulated temperature (> 15°C) is between 1300 and 1500°C, cotton bolls can crack and open normally; when the active accumulated temperature (> 15°C) is less than 1100°C, most of the bolls cannot open normally. The boll weight decreases as the effective accumulated temperature decreases. The boll weight is also affected by fertilizer and water supply.

Lint percentage

Lint percentage is an important yield component and is also correlated with fiber development. It is indicated by the weight of fibers (lint) accounting for the percentage of cotton weight. Thus, it is the relation between the weight of the fiber and the weight of the seeds from which the fiber is obtained in the process of ginning. The lint percentage of mid-maturing upland cotton varieties is 36%–40%. Lint percentage is mainly determined by genetic characteristics of varieties, and is less affected by environmental conditions than boll density and boll size.

Fiber Quality

Main Quality Indexes of Cotton Fiber

Fiber length

Fiber lengths of cotton can be determined by hand-stapling or photoelectrical measurement (Munro, 1987; Behery, 1993) while the fibers are still attached to the individual seed (Munro, 1987) or after ginning. Traditionally, staple lengths have been measured and reported to the nearest millimeter. There are four upland staple classes: Short (<21 mm), Medium (22–25 mm), Medium–Long (26–28 mm), and Long (29–34 mm). Pima staple is classed as Long (29–34 mm) and Extra-long (> 34 mm) (Bradow and Davidonis, 2010).

Fiber strength

The inherent breaking strengths of the individual cotton fibers are considered the most important factor in determining the strength of the yarn spun from those fibers (Munro, 1987; Patil and Singh, 1995; Moore, 1996).

Fiber fineness

Fiber 'fineness' has long been recognized as an important factor in yarn strength and uniformity, properties which largely depend upon the average number of fibers in the yarn cross-section (Bradow and Davidonis, 2010). Micronaire is an indirect estimate of fiber fineness and maturity.

Factors Affecting Fiber Quality

The fiber quality of cotton is a composite property determined by complex interactions among (1) the genetic potential of the genotype, (2) the environmental fluctuations experienced by the maternal plant from planting through harvest, and (3) the genetically controlled responses of the genotype to the environmental fluctuations (Bradow and Davidonis, 2010). As do all metabolizing plant cells, a cotton fiber cell responds individually to fluctuations in the macro- and micro-environments so that the fibers on a single seed constitute a continuum of fiber lengths, shapes, cell-wall thicknesses, and maturities (Bradow *et al.*, 1997a,b). Environmental changes among plants, and within and among the fields assure that each bale of cotton contains a highly variable fiber population that contains a wide range of fiber-quality characteristics. Therefore, the natural genetic and physiological changes in fiber cell shape, size, and maturity are regulated by fluctuations in the growth environment (Bradow and Davidonis, 2010).

Traditional Field Management for Cotton Production

Pre-Sowing Preparation

Pre-sowing preparation for cotton includes preparation of land, seed and other materials for production, and determination of sowing date. Land preparation includes deep tillage, leveling and irrigation; seed preparation includes selecting good seeds, doing germination test and solar drying of seeds before sowing. Sowing date should be determined comprehensively according to soil temperature and moisture.

Sowing and Plant Density

Cotton is planted by machines or manually. The planter opens a small furrow in each row, drops in seed, covers them, and then packs more dirt on top. Seed may be deposited in either small clumps (referred to as hill-dropped) or singularly (called drilled). The seed is placed 2–3 cm deep, depending on the soil type.

Plant density is an important factor influencing cotton yield and yield components. Lint yield is relatively stable across a wide range of plant densities. The planting density should be determined according to plant and ecological condition, planting methods and cotton varieties.

Fertilizer Use

Nitrogen (N), phosphorus (P) and potassium (K) are the essential nutrients required most consistently for cotton production. The absorption of N, P and K is 4.5, 3.0 and 4.0% of the whole growth period at the seedling stage; 28%–30%, 25%–29% and 28%–32% at the squaring stage; 60%–62%, 64%–67% and 62%–63%, at flowering and boll-setting stage which is the key period for yield formation; and 3.0%–8.0%, 1.0%–7.0% and 1.0%–6.0%, at the boll-opening stage. Thus, rational use of basal fertilizer and moderate topdressing is an important measure to improve cotton yield and fiber quality.

Irrigation

Cotton is one of the most tolerant crops of drought stress, but it responds well to water application. Timing of drought stress appears to be more important than total amount of water available to the crop. During early seedling growth, cotton can withstand long periods with minimal water and growth and yield will not be greatly affected. However, once squaring begins, drought stress will cause square and boll abortion and dramatically affect its growth and yield. Square and boll shedding is especially important in areas with short growing seasons since the plants may not have enough season left to develop more bolls at the top of the canopy. Severe soil water deficit can reduce fiber length and micronaire value. Since cotton responds to water stress by abscising squares and bolls, few bolls develop under severe water stress conditions. Thus, the impact of water stress on fiber properties appears to be smaller than that on lint yield (Bauer, 1994).

Water requirement

Water requirement refers to the amount of water consumed in the field during the growth and development of cotton. It is the total amount of water used by cotton and the amount of transpiration and evaporation during the whole growth period. The required amount of water at different growth stages varies with environmental conditions. The water requirement at the seedling stage is less than 15% of the total requirement for the whole growth period; it is 12%–20% at the squaring stage, 45%–65% at the flowering and boll stage and 10%–20% at the boll opening stage.

Irrigation techniques

The predominant methods for application of supplemental water to cotton are furrow irrigation, overhead sprinkler irrigation and drip irrigation. In furrow-irrigation systems, water is applied through gated pipes from one end of the field and allowed to flow down row middles. Overhead sprinkler systems travel through the field applying water above the canopy. Micro-irrigation pipe, which can be buried or placed on the surface, places small amounts of water in the rooting zone of the plants, eliminating water loss through evaporation and through leaching.

Plant Growth Regulation

The cotton plant can produce excess vegetative growth under high soil moisture and fertility. Excess growth can lead to boll and square shedding. Plant growth regulators are organic compounds other than nutrients that affect physiological processes of plants when applied in low concentrations. For cotton, growth regulators are used to control vegetative development and to improve maturity in the late season. For example, Mepiquat chloride has been widely used to regulate cotton growth and development.

Harvesting and Processing

For centuries, cotton harvesting was done by hand. Cotton had to be picked several times in the season because bolls do not completely ripen at the same time. Today, more and more cotton is mechanically harvested.

Cotton plant should be defoliated if it is to be machine harvested. Defoliation (removing the leaves) is often accomplished by spraying the plant with a chemical. It is important that leaves not be harvested with the fiber because they are considered “trash” and must be removed. In addition, removing the leaves minimizes staining the fiber and eliminates a source of excess moisture. Without defoliation, the cotton must be picked by hand.

Harvested cotton needs to be cleaned before ginning. Often, it is dried before being put through the cleaning equipment which removes leaves, dirt, twigs, and other unwanted materials. After cleaning, the long fibers are separated from the seeds with a cotton gin and then packed tightly. Cotton is classified according to its staple (length of fiber), grade (color), and character (smoothness). In the textile mill, cotton fibers are spun into yarn and then woven or knitted into cloth. The seeds, still covered with linter, are sent to be pressed in an oil mill (Fig. 3).

Fig. 3 Cotton harvesting (*Left*) manual picking; (*Right*) mechanical harvesting.

Specific Cultural Practices for Improved Yield and Fiber Quality

Intensive Culture

Intensive farming technologies and cultural practices in cotton are widely adopted in China and some other developing cotton growing countries. They mainly include seedling transplanting, plastic mulching, plant pruning and super-high plant density technique (Dai and Dong, 2014).

Seedling transplanting

The seedling transplanting process mainly consists of three steps: raising of seedlings in nursery beds, transplanting seedlings to the fields, and field management after transplanting (Dong *et al.*, 2007). Generally, transplanting is carried out when the mean soil temperature at the 5 cm depth reaches 17–19°C and cotton seedlings have 2–4 true leaves on the main stem. Soon after transplanting, the field is watered to let seedlings recover normal growth quickly.

Plastic mulching

Plastic mulching is usually done soon after sowing. Seedlings are freed from mulching cover by cutting film above hills at emergence, and thinned to the planned population density by leaving one vigorous plant per hill at the two-leaf stage (Dong *et al.*, 2009). Generally, the polythene mulch can be retained during the whole growth season, especially in arid and special early maturing cotton areas to improve soil temperature and decrease moisture evaporation. In areas with ample water and heat sources, plastic film should be removed at full squaring.

Plant pruning

Plant pruning mainly involves removal of vegetative branches, plant topping, and excising old leaves and empty fruit branches. It can efficiently coordinate the relationship between vegetative and reproductive growth by adjusting the distribution of nutrients in plant tissues, and reducing the nutrient consumption by surplus organs. Plant pruning could also improve the microclimate of the cotton field, reduce boll abscission and boll rot (Li *et al.*, 2007) and increase cotton yield and fiber quality (Zhou and Yang, 1999).

Light and Simplified Culture

During the last two decades of the 20th century, the adoption of intensive cultivation technologies has helped China to enhance yields and emerge as the world's largest cotton producer. But this approach is being debated now because of the increasing labor costs which are linked to the rapid economic development and urbanization of the country. A new approach called 'light and simplified cultivation' (LSC) has been initiated to respond to the new context. This approach has become more relevant to the small-scale farming systems of China as opposed to the complete mechanization observed in developed countries. The approach of LSC aims to reduce labor intensiveness. It simplifies field management, diminishes the frequency of field operations, and adjusts techniques that blend with their implementation by machines (Dai *et al.*, 2017). The key technologies of LSC in cotton cropping include precision mono-seeding technology, light and simplified seedling nursery technology, non-pruning technology, one-time fertilization technique, fertigation technology and technology for plant population management (Dong and Fok, 2018).

Precision mono-seeding is based on using high-quality seeds sown as single-seed per hill on finely prepared soil-beds, at row spacing defined for mechanical sowing (Kong *et al.*, 2018). This technique is applied through diverse modalities depending on regions.

The non-pruning technology consists of setting up a large population of small individual plants whose growth is properly regulated. By LSC approach, the development of vegetative branches can be greatly inhibited by increased plant population density instead of traditional plant pruning.

One-time fertilization technique in the LSC approach refers to a reduction in the number of fertilizer applications and the amounts of fertilizers under various conditions, depending on regions and yield targets.

In short, the development and application of LSC are indispensable for sustainable cotton production in China in view of the scarcity and higher cost of labor. For the techniques already operational, the shift from the intensive cultivation system to LSC is significant. LSC technology is believed to provide a solid support for sustainable production of cotton in China and holds tremendous promise for field-enhancement in the small-scale farming systems in Africa (Fig. 4).

Distinctive Cotton

Organic Cotton

Organic cotton is generally understood as cotton from non-genetically modified plants, which is certified to be grown without the use of any synthetic agricultural chemicals such as fertilizers or pesticides. Its production also promotes and enhances biodiversity and biological cycles. In the United States, cotton plantations must also meet the requirements enforced by the National Organic

Fig. 4 Non-pruning cotton field under high plant density and chemical topping.

Fig. 5 Colored cotton and white cotton.

Program (NOP), from the USDA, in order to be considered organic. This institution determines the allowed practices for pest control, growing, fertilizer use, and handling of organic crops.

Colored Cotton

Nearly all of the cotton fiber used for textiles is white; consequently, dyes are required during the processing of fibers to color cloth. The enormous consumption of dyes has resulted in environmental pollution and has thus negatively affected human health. One of the most efficient solutions is to breed cotton varieties that naturally contain colored fibers (CCFs), which are environmentally innocuous.

One of the most important factors that differentiate CCFs from white cotton fiber (WCF) during fiber maturation is pigmentation. Many factors are involved in pigmentation, including the type of pigment, the activity of phenylalanine ammonia lyase, the concentration of total carbohydrates, and the type of soluble saccharide (**Fig. 5**).

Better Cotton

Better Cotton was developed by the Better Cotton Initiative (BCI) of Switzerland to help farmers to grow cotton in a way that reduces stress on the local environment and improves the livelihoods and welfare of farming communities. Better Cotton exists to make global cotton production better for the people who produce it, for the environment it grows in, and for the sector's future. The Better Cotton Production Principles and Criteria lay out the global definition of Better Cotton, by upholding the following six principles in which it is produced by farmers who:

- (1) Minimize the harmful impact of crop protection practices.
- (2) Use water efficiently and care for the availability of water.
- (3) Care for the health of the soil.
- (4) Conserve natural habitats.
- (5) Care for and preserve the quality of the fiber and Promote Decent Work.

Conclusions

Cotton fiber is one of the most important raw materials in the textile industry. It is also a renewable natural resource; for this reason, cotton is widely grown in the world. The growth and development stages of cotton consist of emergence, seedling, squaring, flowering, boll-setting and boll opening stages, which totally last for 180–200 days. Cotton yield is formed through fruiting. The basic components of lint yield are the number of bolls per unit land area, weight per boll and lint percentage. Quality of cotton fiber can be mainly indicated by fiber length, fiber strength and fiber fineness. Comprehensive factors such as environment, planting system, agronomic measures and harvesting regulate every developmental process of the cotton plant, both vegetative and reproductive growth, and also affect the yield and quality of cotton fiber. Thus, to achieve maximum yield and quality of cotton fiber, appropriate combination of genotype, environmental conditions and cultural practices like light and simplified culture should be adopted.

Bamboo: The Emerging Renewable Material for Sustainable Construction

Yingxin Goh, Soon P Yap, and Teong Y Tong, University of Malaya, Kuala Lumpur, Malaysia

© 2020 Elsevier Inc. All rights reserved.

Introduction

In recent years, green concept is being advocated extensively by environmentalists. Energy cut down and reduction of carbon dioxide (CO₂) emission are the examples of green concept which are always promoted to help the sustainability of our mother earth. According to the National Aeronautics and Space Administration (NASA), the heat trapping nature of CO₂ and other greenhouse gases has been demonstrated in the mid-19th century. Hence, to protect our earth, the use of environmental-friendly construction material has been promoted. One of the criteria being the environmental-friendly construction material is by having the potential in reduction of CO₂ emission during its production.

The term “sustainability” also refers to development that are capable to meet the current generation’s demands by not undermining the ability of the future generation to meet their own needs (def: as per agenda 21, World Climate Summit in Rio de Janeiro 1992). Therefore, in terms of this social sustainability of not undermining the future generation’s ability of using the resources, the use of renewable resources is always being enhanced. Last but not least, in terms of sustainability of economics, strategies for employing existing resources optimally to achieve long-term responsible and beneficial balance was always being encouraged to be executed. Due to the limitation supply of resources, the construction material’s price was always increasing. This subsequently has increased the burden of the developing country. As a result, there is always an urge to explore for new green construction materials to substitute the conventional materials.

In summary of the above criteria, bamboo, is considered as one of the new emerging materials which possess a great economic potential. Structural bamboo has been traditionally used in China, India, Philippine and Latin America for hundreds of years. It has been utilized as structural members in short-span footbridge, low-rise houses, long span roof and construction platforms. Besides, it is also exploited in signage erection, decoration, demolition, and civil works. One of the popular usages of bamboo in the South-East Asia, especially, in Hong Kong and Southern China is the construction’s access scaffoldings (Chung and Yu, 2002). The high productivity rate and short cycle of harvest enables bamboo to be an outstanding material compared to the other naturally growing resource. On top of that, bamboo has been proven that having its ultimate tensile strength on par with the mild steel (Baksy, 2013). Moreover, the ratio of tensile strength to the density of bamboo is 6 times higher than that of steel. Its high strength-weight ratio supports it to be used as a high resilient material against force generated by earthquakes and wind of high velocity.

Bamboo Species

Botanical Classification

Bamboo is a giant, perennial, woody grass categorized in angiosperms group of monocotyledon order (McClure, 1966; Liese, 1987). It is an evergreen flowering plant belonging to the grass family Poaceae (formerly Gramineae), subfamily Bambusoideae and tribe Bambuseae. It is the largest member in the grass family. Bamboo is characterized by joint stems called culms. The internodal parts of the stem are typically hollow and instead of in a cylindrical arrangement, the vascular bundles are scattered throughout the cross section of the stem. As it is monocotyledon, there is no dicotyledonous woody xylem. Consequently, rather than tapering, the lack of secondary growth brings up the stems of monocots to be columnar.

As characterized by the formation of upright canes and types of rhizome, there are generally two main categories of bamboo. The first category is monopodial bamboos, also known as running bamboos. They generally have long and thin rhizome extensions whose buds producing single shoots at regular intervals. They usually grow in scatter state and spread over a large distance. The second category is sympodial bamboo. It has short, thick rootstocks where axillary buds are formed which then developed into new stems. They usually grow in clumps. Owing to its unique rhizome-dependent system, bamboos are listed as one of the most rapid growing plants. It constitutes more than ten genera which are further categorized into about 1450 species.

Growth of Bamboo

The growth pattern of bamboo is a combination of leaf-bearing tree, palm and grass. Like leaf bearing trees, bamboo shed their leaves every year and by throwing out new branches that increase their crown each year. Due to the absence of secondary woody xylem, and it has its definitive circumference emerging from the soil, its diameter would not increase afterwards. On the other hand, bamboos are like grasses where they have tubular blades, and lancet-shaped cover leaves. The characteristics that differentiate bamboos from grasses are the lignification, branching and longevity of their canes (Patil and Mutkekar, 2014). Bamboos have a growth area of about 38,000 million ha, which covers approximately 3.2% of the total forest area around the world. Bamboo grows naturally in tropical and sub-tropical regions and is commonly found in Asia, with 65% of the total world bamboo

resources, followed by Central and South America with 28% and Africa with 7% (Correal, 2016; Richard, 2013). Although most bamboo resources grow naturally, increasing attention has been given to planted bamboo these few decades. In Asia, approximately 30% of total bamboo resources are planted (Table 1) (Lobovikov et al., 2007). This percentage has remained stable over the reported period with only a very slight increase in 2005. It is worth noticing that all of the bamboo forest in Malaysia is reported to be naturally regenerated. No data were reported on planted bamboo in Malaysia but there is only a fine separation line between categorization of planted and naturally regenerated bamboo, and it requires further clarification.

Bamboo Species in Malaysia

Malaysian bamboos generally belong to the sympodial bamboo category. It is reckoned that in Peninsular Malaysia there are around 59 bamboo species which originates from 7 genera, i.e., *Bambusa*, *Dendrocalamus*, *Dinochloa*, *Gigantochloa*, *Racemobamboos*, *Schizostachyum* and *Thyrsostachys*. Fig. 1 illustrates the bamboo forest distribution in Peninsular Malaysia and the distribution data is also presented in Table 2.

Based on Table 2, the Kelantan state is found to have the highest density of bamboo within forest districts in Peninsular Malaysia, comprising of 31,035,850 culms. This is followed by Pahang (23,480,760 culms), and Perak (20,174,160 culms). The total number of culms in Peninsular Malaysia was 110,584,140 covering 421,722.38 ha of forest areas (Lockman et al., 1992). The most useful bamboo found in these areas is *Gigantochloa scortechinii*, which can be found in the Kedah, Kelantan, Perak, Selangor and Terengganu states.

Bamboo Species Currently Used in Construction in Asia

Only specific species of bamboos are suitable for application in construction. Below is the list of bamboo species that are recommended to be used as construction materials:

- *Bambusa oldhamii* – Or more well-known as the Giant Timber Bamboo. This tall species from China can grow up to around 65 ft high with a maximum diameter of 4 in.
- *Bambusa Lako* – Can grow up to 50 ft high and has a useful 4-in. diameter. As it able to retain its black color even after being harvested, it is widely used in furniture making.
- *Dendrocalamus Asper* – A very strong species from Southeast Asia and is known to grow as tall canes that have long straight sections of approximately 65–100 ft and diameter of around 3–8 in.
- *Dendrocalamus Brandisii* – Boasting canes that can grow tall and straight, can reach a height of approximately 60 ft and diameter of 6–8 in. It is an excellent building material and is one of the species that can be found throughout regions of Southeast Asia.
- *Dendrocalamus Yunnanicus* – This species has strong and straight canes that can grow to around 70 ft high. It is good for bamboo lumber and is a great species as construction industry materials.
- *Gigantochloa Apus* – It can grow up to around 60 ft high and 4-in. diameter. This is a species that has been traditionally used as an Indonesian building material.
- *Gigantochloa atrovioleacea* – It is a very straight growing plant, with strong black canes that will grow to a height of approximately 50 ft and a good 4-in. diameter. It is a species that is good for furniture making.
- *Gigantochloa Atter* – A species that has straight and strong canes and can reach an approximate height of around 60 ft and 4-in. diameter.
- *Gigantochloa Pseudoarundinacea* – An excellent bamboo species from Indonesia and have boasting canes that can grow up to 40 ft high and 4 in. in diameter.

Fig. 1 Bamboo forest distribution in Peninsular Malaysia. Reproduced from Lockman, M.S., Shahwahid, H.O.M., Poh, L.Y., Saroni, J., 1992. Distribution of bamboo and the potential development of the bamboo industry. In: Proceedings of the National Bamboo Seminar I. Towards the Management, Conservation, Marketing and Utilization of Bamboos, pp. 6–19. Kepong, Kuala Lumpur, Malaysia: FRIM.

- *Gigantochloa scortechinii* – A bamboo species found in Indonesia, central and northern Peninsular Malaysia, as well as southern Thailand. Can erect up to 70 ft tall and have a diameter within the range of 5–8 in. at maturity.
- *Phyllostachys bambusoides* – This is also a giant timber bamboo originating from China that can grow up to approximately 70 ft tall and around 5 in. in diameter.

Anatomy of Bamboo

Since bamboo is a very versatile plant, all parts of the plant can be utilized fully as depicted in Fig. 2 (Correal, 2016). The two main anatomy structures of bamboo are culms and rhizomes. Culms are the parts of bamboo above ground. For construction materials purpose, culms are usually the one that are taken. Along the culm of bamboos, it is separated by solid transverse diaphragms called nodes (Fig. 3). Typically, the length of internodes increases along most of the culm height, and decreases as it reaches the top of the culm (Amada *et al.*, 1996). The cortex of the bamboo culm generally contains shorter cork, axially elongated cells, silica cells, and stomata. The cells in the internodes are composed of approximately 50% parenchyma, 40% fibers and 10% conducting tissue (Liese, 1985).

Note: Lockman, M.S., Shahwahid, H.O.M., Poh, L.Y., Saroni, J., 1992. Distribution of bamboo and the potential development of the bamboo industry. In: Proceedings of the National Bamboo Seminar I. Towards the Management, Conservation, Marketing and Utilization of Bamboos, pp. 6–19. Kepong, Kuala Lumpur, Malaysia: FRIM.

Bamboo is a functionally graded material which has evolved naturally to resist the primary loading, i.e., the lateral wind loading and its own weight. This can be justified as the fibers density increases from the inside wall to the outside wall of the bamboo culm. Besides, in some species (e.g., *Bambusa blumeana*), the bamboo culm has the thickest culm wall at the base and decreases with height up along the culm. This shows the natural inherence of bamboo in gravity load reduction while maintaining the resistance for lateral wind loading (Richard, 2013). Although the fiber amount reduces from bottom to the top of bamboo culm, the bamboo fiber density does increase with height due to the tapering of bamboo culms from base to top. It was known that the ratio of fiber length to width lies between 150 and 250. This ratio varies with the species and location along the bamboo culm (Liese, 1985).

The performance of bamboo is highly related to its structure and fiber orientation. At the macro level the bamboo culm can be seen as a typical unidirectional reinforced composite with the fibers as the reinforcing phase and the supporting tissue (parenchyma) as the matrix material. On the other hand, at the meso-level, it can be seen in the cross-section of the bamboo culm wall that the fiber bundles that form a protecting sheath around the vascular bundles are distributed densely in the outer region of the wall, sparsely in the inner region, and are more concentrated in the upper part of the culm compared to the base (Osorio et al., 2018; Liese, 1998). Similar to other natural fibers, bamboo fiber is a bundle of elementary fibers bonded together by the middle lamellae (Fig. 4). Each elementary bamboo fiber wall possesses a unique multilayer configuration called polylamellate structure which contributes to the strength and modulus of the bamboo culm (Osorio et al., 2018; Liese, 1998). It is also worth noticing that the proportion of lumen tends to be higher towards the fiber bundle periphery (Fig. 4(a)). Hence, in processes involving extraction of bamboo fibers, it is desirable to remove these peripheral elementary fibers because the presence of big lumens may lead to voids in the final composite (Osorio et al., 2018).

In-depth study of the microstructure of bamboo fibers and their relation to the mechanical properties. *Journal of Reinforced Plastics and Composites* 37, 1099–1113.

Mechanical Properties of Bamboo

It is a well-known fact that bamboo is one of the natural resources that has outstanding mechanical properties. This is attributed to the cellulose which is the main constituent in bamboo. It has also been discovered that bamboo can perform well in buckling due to the high energy absorption at the joints which created much lower stresses compared to steel. Therefore, the failure of bamboo at seismic zone is very rare.

Tensile strength

It has been experimentally proven that some species of bamboo can have an ultimate tensile strength comparable to mild steel, which falls within the range of 140–280 MPa (Patil and Mutkekar, 2014). Since the bamboo is a functionally graded material, tensile tests are usually conducted on cut-out strips at different locations along the height. From the work done by Amada *et al.* (1996,1997) on two years old *Phyllostachys edulis* Riv. (Mouso bamboo), it was found that the tensile strength obtained is within 140–230 MPa, which was much higher than that of common woods such as fir, pine, and spruce (~30–50 MPa). The strength of the inner bamboo region is found to be 80 MPa and increases parabolically with radial distance. Assuming that the mixture principle of composites can be applied to the bamboo culms, the extrapolated data shows that the tensile strength of vascular bundle can be 610 MPa which is around 12 times higher than the lignin matrix tensile strength (50 MPa) (Amada *et al.*, 1997, 1996).

As compared to the internodes of bamboo culm, bamboo nodes exhibit rather more isotropic behavior due to their entangled fibers. Nevertheless, lower tensile strength also recorded in this region (Amada *et al.*, 1997). It is also worth noticing that bamboos have rather weak tensile resistance at directions perpendicular to the fiber arrangement. When tension force is exerted in the transverse direction, the only element that acts to resist the tensile stress is the lignin matrix. This corresponds to splitting and cracking failures. According to Arce (1993), bamboo has shown to fail at a specific transverse strain of about 0.001. This value should therefore be used as a limiting criterion in the structural design. Besides, this value can also be correlated to bamboo's longitudinal direction performance since bamboo was known to have a stable Poisson's ratio of around 0.3 (Janssen, 1981).

All in all, bamboo is able to withstand more tension than compression. As the bamboo fibers run axially and its outer zone are densified with highly elastic vascular bundles, it has a relatively high tensile strength. The tensile strength of these fibers is comparable or even higher than that of steel, but it should be noted that it is rarely possible to construct connections which is able to transfer this high tensile strength (Patil and Mutkekar, 2014).

Compressive strength

The full-culm bamboo's compressive strength has been studied by many authors. Chung and Yu (2002) has studied the variation of compressive capacity against different physical properties of the bamboo culms for two species. For *Bambusa Pervariabilis* (Kao Jue), the compression capacity is found to be at its maximum of about 60 kN at the bottom of the culm, and reduced steadily to about 30 kN at the top. While for *Phyllostachys Pubescens* (Mao Jue), the compressive capacity is reduced steadily from 100 kN at the bottom to 50 kN at the top of the bamboo culm. When the bamboo is tested in wet condition or with high moisture content, it is prone to fail in the end-bearing mode (Fig. 5(a)). On the other hand, if the bamboo is tested in dried condition or with low moisture content, it will usually fail in the splitting mode as the cracks occur along the bamboo's fiber (Fig. 5(b)) (Chung and Yu, 2002). Janssen (2000) suggested that the ultimate compressive stress of air-dry bamboo can be estimated using Eq. (1).

$$f_c = 0.094\rho_{air-dry} \quad (1)$$

Fig. 5 Post-compression test images of bamboo with (a) end-bearing and (b) splitting failure mode. Reproduced from Chung, K.F., Yu, W.K., 2002. Mechanical properties of structural bamboo for bamboo scaffoldings. *Engineering Structures* 24, 429–442.

where f_c = ultimate compressive stress (MPa).

$\rho_{\text{air-dry}}$ = density of air-dry bamboo (kg/m^3).

Arce (1993) states that under compression test, lignin plays a significant role in bamboo failure as critical tangential strains was induced by the tangential expansive forces. For a typical compression test, the specimens are usually bulge laterally (like a wooden barrel) and develop vertical cracks. During the experiment, as the friction loading plates with the specimen together can affect the corresponding compressive strength value. For more accurate compressive strength data collection, it is suggested that friction-free loading plates should be used during the testing.

Elastic modulus

Bamboos with high elastic modulus is claimed to be of high quality. The high elasticity of bamboo is advantageous to be applied as building materials, especially in earthquake-prone areas (Patil and Mutkekar, 2014). There is a worldwide call for the use of better and sustainable building materials to rebuild safely and cost-effectively in post-disaster reconstruction programs, and one of the materials suggested is bamboo.

Generally, the Young's modulus against compression loading of bamboo is observed to vary steadily from 5 to 35 GPa from the base to the top of the culms. Research has been done on developing equations to account for the relationship between bamboo fibers number and its gradation with the bamboo elastic modulus. Janssen (2000) has reported that for the same volume of fibers, the functional gradation of bamboo fibers across the cross section has contributed to the 10% increase in stiffness. The densification of strong fibers in the outer parts of bamboo tube wall has a positive impact on the elastic modulus. Since the elastic modulus for cellulose is about 70 GPa and by assuming a bamboo fiber is of 50% cellulose, thus the apparent or effective modulus, E is approximated to 35 GPa. This value is then multiplied by the fibers percentage in the inner and outer layers of the culm (Janssen, 2000). Another way is to determine the bamboo fibers volume fraction across the wall thickness. The modulus of elasticity is then determined by the rule of mixtures (Amada *et al.*, 1996; Ghavami, 2008).

Flexural strength

For air-dry bamboo, the ultimate bending stress was estimated by Janssen (2000) using Eq. (2).

$$f_b = 0.14\rho_{\text{air-dry}} \quad (2)$$

where f_b = ultimate bending stress (MPa).

$\rho_{\text{air-dry}}$ = density of air-dry bamboo (kg/m^3).

Yet, in typical bamboo bending tests, the critical failure mode is not fiber fracture, but the longitudinal splitting of material. This was due to fracture of the weaker lignin which bonds the fibers together as shear in the section overcomes the lignin capacity. A critical transversal strain value of 0.0013 was reported to be the bamboo's bending capacity. Meanwhile, a critical value of 0.00373 for longitudinal strain and 62 MPa for ultimate bending stress are estimated based on the typical test outcome using a modulus of 17 GPa and Poisson's ratio of 0.3 (Janssen, 2000).

Shear strength

As mentioned before, the strength of the lignin matrix is always the bamboo strength restraining factor. Due to hollow cross section, bamboo culm has less cross-sectional area to resist shear compared to timber, despite the fact that bamboo lack of defects such as knots. Since bamboo fibers are unidirectional, bamboo culm has two asymmetric shear planes: one parallel to the fibers and another across the cross section. Hence, for the application of bamboo in construction, shear strength and longitudinal splitting are the important factors to be considered. A critical shear stress value of 2.2 MPa at the neutral axis was estimated by Janssen (2000) while the bamboo culm is in bending mode.

Bamboo as a Building Material

Nowadays, the adoption of bamboo as a structural material has been gaining considerable attention. The society is now emphasizing a lot on the use of green materials in each and every aspect, and the construction sector shall not be excluded as well. This is extremely important because the construction sector has been deemed as one of the prime sectors that contribute to the global carbon dioxide emission. Owing to this, green construction materials are always invented to replace the conventional building material. This is commonly achieved by the inclusion of industrial and agricultural by-products such as into the concrete production. Examples of industrial by-products include slag and fly ash; while agricultural by-products include rice husk and palm oil wastes (fiber, shells, clinker, fuel ashes). Apart from inventing new green materials, the use of natural resources has also gained the attention from the public. It is the new emerging material discussed in this article, bamboo.

In the construction industry, cost is one of the main criteria for material selection. Bamboo can be classified as an economic building material due to its high productivity rate and short cycle of harvest compared to other naturally growing resources. This was justified by researchers as that if structural bamboo plants were planted today, in about 3–4 years later mature clumps of bamboo plants will be available, and within 8 years, sufficient mature materials would be available to set up a low cost and reliable structure (Richard, 2013). Besides, the high tensile strength and excellent weight to strength ratio of bamboo are the prominent characteristic for it to be considered as potential building materials. The excellent weight to strength ratio enables it to be used as a high resilient material against dynamic forces created by earthquakes and high velocity winds. Furthermore, with these characteristic features, it is able to withstand up to 3656 kg/cm² of pressure.

When it comes to real life application of bamboo as building materials, the main concern would be the natural durability of bamboo. Bamboos generally have low natural durability (1–3 years) because they are prone to being attacked by fungi and insects. They are very difficult to be treated by normal preservative methods in dry condition since their outer and to some extent inner membranes are impermeable to liquids (Liese, 1985). However, elements made by bamboo can generally have a durable life of 30–40 years if it was properly treated and industrially processed. The treatment of bamboo will be discussed in detail in Section “Treatment of Bamboo”.

The idea of applying bamboo in construction used to be confined to the rural construction in developing countries, such as houses, school buildings, community buildings and bridges (Amada *et al.*, 1996). This kind of perception has been changed progressively as in modern construction, it has been utilized as reinforcement and shuttering for concrete (Liese, 1985). Due to its inherent superior properties, being biodegradable, regenerating, lightweight, and high tensile strength, bamboo has been used as building material since long time ago. These innumerable qualities are deemed as a treasure property that it should be enhanced and developed as a popular building material. Some main applications of bamboo in structures include:

- Foundation: Pre-treated bamboo poles are directly driven into the ground (Iyer, 2002).
- Roofing: The simplest form of bamboo roofing is bamboo tile roofing, where the culms are split into halves, the diaphragms scooped out and these run full length from eave to ridge (Fig. 6). The first layer of bamboo splits is laid concave side up and the second layer interlocks over the first with convex side up, and the resultant bamboo roof is completely waterproof (Iyer, 2002; Pande and Pandey, 2008).
- Trusses: For the spanning of larger distances such as in public utility buildings like schools, storage areas, commercial buildings, bamboo is utilized as a truss member. It was experimentally proven that bamboo’s strength is on par with timber, where the 4-meter-long span truss was tested with various jointing techniques for connections web-chord (Iyer, 2002; Patil and Mutkekar, 2014).
- Walls, Doors, Windows, Flooring and Ceiling: There are several bamboo wall building techniques developed, such as *Bajareque* wall, bamboo board wall, *Wattle* wall, mat wall, and solid wall. The higher resilience of bamboo culms made them better than conventional timber to be used as floor beams (Iyer, 2002). The use of bamboo as doors, windows and ceiling materials is particularly popular in countries with warm climate because of its low-heat transmission and high insulation properties, providing an energy saving cool interior atmosphere.

Further applications of bamboo which are relevant to construction encompass its use as scaffolding and water piping. Hong Kong is well known as the country that is widely using bamboo scaffoldings in construction, including the construction of skyscrapers (Fig. 7). It takes only about a day to put up a 1000 ft tall scaffold using bamboo and Hong Kong uses up about 5 million bamboo rods, each 7-meter-long, every year. Bamboo rods are advantageous over iron rods because they are cheaper, faster to build, and easier to transport. Despite their appearance, bamboo rods are actually safer, as they are much lighter than iron rods and cause less damage if they fall.

Advantages of Bamboo as Structural Material

It was known recently there is new wave of trend promoting the use of bamboo as structural material. It was undeniable that bamboo is a remarkable material as it possesses many prominent features which surpass the properties of the usual used materials. There are four main features that makes bamboo an advantageous structural material:

- (1) It is a sustainable material. Besides being a renewable resource, it is also the world's fastest growing woody plants. It grows 3 times faster than most other species and usually only takes 3–6 years to harvest. Therefore, it is believed that the use of bamboos can help in mitigating the pressure of ever-shrinking natural forests and conserve the global environment (Richard, 2013).
- (2) It is an environmental-friendly construction material. Bamboo is a good carbon sequestration agent as it can sequester as much as 12 tons of CO₂ per hectare. Besides, it also generates almost 35% more oxygen than equivalent stands of trees (Osorio *et al.*, 2018). With this feature, it was believed that bamboo can play a role in climate change mitigation and protecting the environment.
- (3) Bamboo is an economical material as it costs lower than most of the construction materials, such as steel. While having comparable strength, less energy is required to harvest and transport bamboos, thus manufacturing costs would be much lower compared to steel. The energy for production of bamboo compared to other building materials is shown in Table 3. It is evident from the data in Table 3 that steel has the highest production energy-to-stress ratio, followed by concrete and wood. Bamboo, on the other hand, has the lowest production energy-to-stress ratio. This shows that bamboo structures are highly energy saving compared to steel structures, with 98% energy saving in terms of production energy-to-stress ratio.
- (4) Bamboo has been proven to have high tensile strength. It is claimed that bamboo has a tensile strength of around 193 MPa, which is on par with the tensile strength of 159 MPa for mild steel (Liese, 1998). This desirable performance of bamboo has

Table 3 Energy for production of different building materials

Material	Energy for production (kg/m ³)	Service stress (N/mm ²)	Production energy-to-stress ratio
Steel	234,000	160	1500
Concrete	1920	8	240
Wood	600	7.5	80
Bamboo	300	10	30

Note: Janssen, J., 1981. Bamboo in Building Structures (PhD). Eindhoven University of Technology.

enabled it to be termed as the “green steel”. The high strength-to-weight ratio of bamboo even allows it to be applied as a high resilient material against the high-speed wind and earthquake force.

Research Development in Structural Bamboo

Bamboo has been used extensively as construction materials but little research was reported. The most significant milestone in the development of bamboo as construction material is the composing of the first bamboo testing standard in 1973 by the Bureau of Indian Standard, IS:6874. Then, the International Network for Bamboo and Rattan (INBAR) was established in 1997 and the gap in knowledge and building codes for bamboo has been filled up gradually. In year 2004, INBAR published several international building codes for bamboo (ISO 22156:2004(E), ISO 22157-1:2004(E)). However, it is presently under revision to account for advances since they were first approved.

As the construction industry is moving towards green, sustainable, and low cost materials, bamboo has gradually gain considerable experimental and literature studies over the recent years. A number of reports described bamboo as a smart natural composite material with optimized distribution of fibers and matrices, not just across cross sections but also along member lengths, in resisting environmental loads in nature (Osorio *et al.*, 2018; Amada *et al.*, 1997). There is also a large amount of data on the mechanical properties of various bamboo species (described in Section “Mechanical Properties of Bamboo”), but the data varies from species to species and in most cases, only typical ranges of values were provided.

Janssen (1981, 2000) has made a huge contribution to the compilation of knowledge on mechanical properties of bamboo in 1981 and 2000. The main conclusions drawn in his work is that the strong points of bamboo are its tension axis, compression axis (parallel to grains), bending, and form of cross section. While the weak points of bamboo are its compression axis (perpendicular to grains) and the shear axis. The recommendations to apply bamboo as construction materials is to design based on the strong points and avoid the weak ones (Janssen, 1981). Chung and Yu (2002) studied the variation of compressive strengths along the culm lengths for two bamboo species, Kao Jue and Mao Jue. Among the physical properties studies in their work, moisture content is found to be the most important factor governing the mechanical properties of bamboo. It is found that the physical and mechanical properties are generally constant along the culm lengths in Kao Jue. However, both the physical and the mechanical properties vary significantly along the culm lengths in Mao Jue, and thus, the non-uniformity should be incorporated when assessing their structural behavior. Amada and Untao (2001) studied the fracture toughness of bamboo by inserting a crack perpendicular to the fibers from the outer surface and carried out tensile tests. The fracture toughness is proportional to the volume fraction of the fibers. It is also found that the average value of fracture toughness is about 56.8 MPa m^{1/2}, which is higher than that of aluminum alloys and far higher than that of other woods (Amada and Untao, 2001).

Laroque (2007) presented a design of a low cost bamboo footbridge considering only structural weights. Examples of connections has been studied herein, which shed light on the absence of an optimum solution to transfer loads from one bamboo cane to another. The most traditional “friction-tight rope” method, appear to remain as the best solutions (Laroque, 2007). The industry calls for further researches to find a truly innovative way of connecting bamboos. In terms of design and construction with bamboo, Correal (2016) concluded that the main issues to be taken into consideration are: using bamboo at a proper mature age, the effect of moisture content on the estimation of mechanical properties, using proper treatment methods for preservation and estimating fire reaction and fire resistance of bamboo structures and assemblies.

Treatment of Bamboo

Durability is always the main concerns for the utilization of bamboo in construction. Although natural durability of bamboo usually depends on the types of species, the service life of untreated bamboo can be generally given as below (Liese, 1980):

- 1–3 years for those in direct contact with soil.
- 4–5 years for those protected from exterior exposure.
- > 15 years under very favorable conditions (e.g., internal framing or rendered).

To improve the durability of bamboo, treatment is a must. By having bamboo preservation or treatment, bamboo service life can be lengthened significantly. Generally, the aim of bamboo preservation is to eliminate the bamboo sugar content and other carbohydrate that attract fungi and insects, thus extending the life span of the bamboo structure (Correal, 2016).

In smaller scale or rural area construction projects, traditional (non-chemical) methods such as clump curing, smoking, white washing, plastering and soaking in water have been used. But in large-scale building projects, chemical methods are more suitable for bamboo preservation. However, with the absence of ray cells which form the radial transportation system that allows easy penetration of liquid through the whole wall thickness, chemical penetration into the bamboo culm tissue is rather difficult compared to wood. Still, there are inventions of safe and effective chemical preservation methods involving the use of chemicals such as boric acid, boron and borax. Open tank for cold soaking, modified Boucherie, pressure and heat treatment are the most commonly used preservation methods against biological attack. There are other preservation methods used, but these methods were scarcely reported thus not discussed in this section.

Open Tank Method

This method is also known as the “leaching bamboo” method. It is a simple soaking method and provides good protection for bamboo culms. The solution gets into the culm by diffusion through the ends and partly through the sides. Investigations carried out on the conditions for open-tank treatment indicate that immature bamboo allows much better penetration through both the outer and the inner skin compared to mature bamboo. This effect may be correlated with the amount of lignification. Both the outer and the inner skin are permeable to some extent to 169 preservatives during long soaking; however, the inner skin is a little more permeable than is the outer. Consequently, split culms can be treated more easily than round ones, and the use of split bamboo could reduce the soaking period by as much as one-half (Liese, 1980). It is also suggested that before the immersion process with or without water-soluble preservative for several days, holes should be drilled across each internode to allow better penetration of chemical solution inside the bamboo cavity. This leaching process can reduce the starch content of bamboo besides providing preservative to the bamboo culms.

Modified Boucherie Method

The Boucherie method has long proven to be effective for freshly harvested bamboo culms. The water-transporting part of the culm can be penetrated completely, and the treatment itself needs only few and cheap installations. In the classical form of the method, the preservative is forced by gravity from a container placed higher than the stem through pipes into the stem base. The higher the vessel is fixed, the faster is the penetration. It is also possible to hang the culm vertically or scratch the inner wall of the top internode so that it acts as a reservoir for treatment (Janssen, 2000).

However, the classical method was then modified or improved by the application of pneumatic pressure (air pump). At the bottom of a container, a small, metal tube is fixed from which several other tubes lead to the ends of bamboo culms. The culms are fastened to the tubes by rubber cuffs. The preservative is forced axially through the culm by an air pressure in the container. Compared to the classical Boucherie method, this modified method reduces the treatment time from several days to only 3–8 h (Liese, 1980). Even a simple hand pump or for commercial scale operation, a centrifugal pump can be used for the purpose. Also, the bamboo culm can be treated with or without branches and leaves.

The solution dripping from the top end at the beginning of the experiment will be mainly sap and subsequently the preservative. The chemical solution residue may be recycled once it is cleaned, and chemical solution is added to achieve the original concentration. The treatment is can be deemed completed as the concentration of the solution at the dripping end is about equally to that of the preservative solution.

The advantage of this treatment method is that the equipment used is low-cost, can be easily built, easy to transport and could be used directly in the forest. Moreover, it can be built in different scales, from a handy equipment to treat a few culms to a permanent plant that treats hundreds of culms per day. Furthermore, this method is one of the best in terms of penetration, distribution and retention.

Pressure Treatment

Pressure treatment is carried out in some countries, both with water-borne preservatives and with creosote. It is one of the best preservative methods for bamboo but is also expensive, and may not be economical for low cost materials like bamboo. It is suitable for bamboo treatment in commercial scale especially for high end applications such as fashionable iconic buildings. It requires specialized equipment (an autoclave) that applies pressure ranging around 0.5–1.5 N/mm². However, this treatment method may only be applied to thick-walled bamboos because culms with thin walls tend to crack under the applied pressure.

Heat Treatment

The properties and durability of bamboos were also known to be improved by heat treatment. Typically, this technique involves the immersion of bamboos in hot oil bath at a temperature range of 160–220°C for two to four hours. Vegetable oils with high boiling points such as palm oil, coconut oil and hemp oil is commonly used for this treatment process. However, some work

reported that there is reduction in strength of bamboos if the heat treatment temperature was not handled appropriately (Manalo and Acda, 2009). This could be the reason where this treatment method is less popular compared to other methods.

Future Directions in Structural Bamboo Research

The main reason that bamboo structures are yet to be accepted by the construction industry lies on the durability of bamboos. Bamboos, which is organic in nature, is highly susceptible to degradation and fungi attacks, especially in tropical countries with hot and humid weather like Malaysia. Treatment methods are available but the protection on actual sized bamboo structures have yet to be fully established. Hence, there is a need for a thorough study comparing the efficiency of treatment methods mentioned in Section "Treatment of Bamboo". Also, actual sized bamboo structures must be erected and the structural integrity must be monitored continuously for 5–20 years. The structural health monitoring data will be useful in convincing the public to accept structural bamboos. Last but not least, the final stage of the structural bamboo research is to collect sufficient data to be modeled into a comprehensive bamboo design standard, with complete guideline in terms of bamboo selection, treatment method, stress designs, connection designs, as well as durability check.

Glossary

Biocomposites A composite material formed by a matrix (resin) and a reinforcement of natural fibers.

Bulk molding compound (BMC) Polyester resin/glass fiber premix, for injection or transfer molding, also known as dough molding compound (DMC).

Carbon fiber Reinforcing fiber known for its light weight, high strength and high stiffness.

Composite A material made up of resin and reinforcement (usually fiber).

Fiber reinforced polymer (FRP) A general term for composite materials or parts that consist of a resin matrix that contains reinforcing fibers such as glass or fiber and have greater strength or stiffness than the resin. FRP is most often used to denote glass fiber reinforced polymer.

Fiber A unit of matter of relatively short length, characterized by a high ratio of length to thickness or diameter.

Glass fiber Reinforcing fiber made by drawing molten glass through bushings. The predominant reinforcement for polymer composites, it is known for its good strength, processability and low cost.

Impregnation Saturation of reinforcement with liquid resin.

Polymer A long-chain molecule, consisting of many repeat units.

Recyclates The raw material, collected, taken to and processed in a waste recycling plant or materials recovery

facility which will be used in the manufacturing of new materials.

Recycling The process of converting waste materials into new materials, products and objects.

Reinforcement Key element added to resin (matrix) to provide the required properties; ranges from short fibers and continuous fibers through complex textile forms.

Resin Polymer with indefinite and often high molecular weight and a softening or melting range that exhibits a tendency to flow when subjected to stress. As composite matrices, resins bind together reinforcement fibers.

Scanning electron microscope (SEM) A type of electron microscope that is used to produce enlarged images of a sample by scanning the surface with a focused beam of electrons, like reinforced CFRP samples. When the samples are placed under the microscope, the electrons mix with the constituent atoms within the composite sample. This will produce different signals that contain information about the surface topography and composition of the sample.

Sheet molding compound (SMC) A flat prepreg material, comprising thickened resin, glass fiber and fillers, covered on both sides with polyethylene or nylon film, ready for press-molding.

Thermoplastic A plastic that softens each time it is heated.

Thermoset A plastic that flows and then sets permanently on first heating, as a result of setting up a three-dimensional cross-linked molecular structure, and subsequently will not soften or dissolve.

Introduction

People have the tendency to use resources rather than to reuse or recycle these resources. Recycling has not always been treated as important until recent decades. From building and road construction materials like concrete (Khalid *et al.*, 2017; Letelier *et al.*, 2017; Liu *et al.*, 2013) to composite polymers (Ogi *et al.*, 2007; Wei *et al.*, 2018; Ignatyev *et al.*, 2014), recycling is economically viable. There is an increase in the study of recycling of composite 77 polymers (Knight *et al.*, 2012; Oliveux *et al.*, 2015; Ignatyev *et al.*, 2014), plastic waste (Jaivignesh and Sofi, 2017; Siddique *et al.*, 2008; Rebeiz and Craft, 1995), composite wastes (Halliwell, 2006; Kratz *et al.*, 2017; Meng *et al.*, 2017a,b) and nanocomposites (Hasan *et al.*, 2019). However, there are limitations and issues to recycling composites, particularly the fiber reinforced composites. Historically, the use of composite materials is dated back to about 3000 years ago in ancient Egypt. Natural fiber straws were used as reinforcements to build walls. Over the years, more durable materials were developed and today we have fiber reinforced composites that can also be produced in large scales. In the 1960s, glass fibers were used in large scale production of by mixing glass fibers and very rigid resins. However, in an attempt to save weight of the composite materials, and reduce the cost of composite materials, recycling of composites have been the trend in the past two decades (Brower, 2000; Oliveux *et al.*, 2015; Vieira *et al.*, 2017).

FRPs have great advantages that can be harnessed due to their corrosion resistance and high strength-to-weight ratio (Amaechi *et al.*, 2019a; Xu *et al.*, 2013; Yang *et al.*, 2014; Asmatulu *et al.*, 2014). These materials are applied in offshore applications, automobiles, sports, wind energy, automobiles, and wave energy converters (Zhang *et al.*, 2019; Doyle and Aggidis, 2019; Amaechi *et al.*, 2019b). The need for more sustainable materials led to development in composites. Economically, CFRP composites contribute to the decrease of greenhouse emissions by reduction in fuel consumption as they are used to manufacture

Fig. 1 Wastes from an engineering department workshop showing composite wastes. Courtesy: Lancaster University.

lighter bodies of cars and airplanes. There are also some health, safety, and design requirements during the production of composites generally (Amaechi, 2017; Ye, 2003; Murray, 2018; Job, 2015). According to Hopkins *et al.* (2014), composites are expensive, and the case study of a composite pipe is anticipated to cost approximately £10,000,000 compared with approximately £3,000,000 for the equivalent steel pipe. However, savings arise from the reduction in buoyancy tank size as well as the reduction in the lower riser assembly and upper riser termination assembly sizes. It is anticipated that the biggest cost saving would be as a result of simplifying the installation process as the reeled pipe and the smaller buoyancy tank would require less offshore installation time and smaller installation vessels. That being stated, there is no obvious argument to adopt composites based on cost alone, even with the better performance. The author concluded that the composite pipe cost is comparative to a steel option in the single leg hybrid riser configuration considered.

Currently, there are different classes of composites – Both thermosets and thermoplastics. Due to the need for better mechanical properties of these materials and the need to save some project costs, thus the use of recycled composites. These recycled composites have improved strength properties and other material properties (Wei *et al.*, 2018; Meng *et al.*, 2017a,b; Babafemi *et al.*, 2018). Some of these are due to the fiber orientations been aligned in multidirections and the methods used in manufacturing these recycled composites. The most common method for the recycling of fiber reinforced composites is by pyrolysis. GFRP is mostly considered during recycling because it uses a thermoset resin. Currently, it is not economical to recycle thermoset (CFRP using pyrolysis). Wastes can be generated in factories, workshops, schools, houses and they are collected, sorted, and then recycled. Wastes are generated from manufacturing factories, engineering workshops, scrap yards and all collected for recycling. Figs. 1 and 2 show images of wastes at an Engineering Department workshop and an automotive scrap yard, showing high composite waste materials contents that can be recycled.

Presently, FRP composite recycling has been a current debate in both the composite material industry, and the renewable and sustainable materials industry. This is as a result of the economic impact of the FRP wastes generated from both production and utilization of the FRP material. This is expected, considering the growing demand for more sustainable materials, with regards to the timeline of composite materials, as shown in Fig. 3. The application of FRP composites has risen globally in the production of materials for automobiles, households, airplanes, and in the offshore industry. There is also an increase in the researches on recycling FRP composites. Despite the availability of different types of thermoset composites, there are BMC and SMC readily available. These compounds account for the highest percentage of thermoset composite waste due to their greater applications in different forms. In the automobile industry, the use of BMCs and SMCs has increased to attain lighter cars, which will be more fuel saving.

By definition, reinforced plastics are combinations of polymer resins and reinforcing fibers, including short fibers, cut fibers, chopped fibers, and fabric reinforcement (Osmani and Asokan, 2010; Osmani and Pappu, 2010; Kamaruddin *et al.*, 2017). Generally, FRP composites are known to have increased corrosion resistance, increase strength, improved fire resistance, and are able to form complex shapes, have lighter weight, and ease design due to its functional integration. They can also be made of carbon, glass or fiber, while their matrix can be either thermoset matrix or thermoplastic matrix. Leblanc *et al.* (2015) investigated the recyclability of fiber reinforced thermoplastic composites that are randomly oriented. The authors opined that ROS that have high fiber volume fractions ($> 50\%$) have very high formability and attractive mechanical properties, when compared with long or continuous fiber composites. Thus, these properties help to increase the strength of recycled FRP composites as they have good capabilities in compression molding of complex parts of smaller sizes. Thus, this allows the ease of adjusting the parameters such as tight diameter, wall thickness, and rib. According to Lauzé (2001), the best recycling technique available today is the thermal process called conventional pyrolysis, since it generates recydate

Fig. 2 Wastes from an automotive scrap. Courtesy: Stella Job.

Fig. 3 Timeline on composite applications and processes. Courtesy: Hartman, D., 2014. Advances in reinforcement materials (glass fiber materials). In: Proceedings of the Composites and Advanced Materials Expo (CAMX), October 13-16, 2014, pp. 1-25. Orlando, USA: CAMX.

of excellent quality while being contamination tolerant, highly energy saving, and thus the best option economically. This is quite debatable as the thermal process takes down the fiber molecules and disorientates them. Today, there is no or a restricted deposit (or very few) of carbon fibers from aircraft, at the EOL, as aircraft that integrate such materials are only being constructed at the point and will later become waste (Prinçaud *et al.*, 2014). Connora argues that resin and fiber (e.g., carbon, glass, Kevlar) can be retrieved from epoxy composite goods produced using its Recyclamine hardeners using a “patented, low-energy recycling method.” The parts that are recovered from the epoxy and fiber can be sold, reused, redirected, or repurposed.

“X-Ray” on Recycling Fibre Reinforced Polymer Composites

From a thorough search on peer-reviewed literature on FRP composite recycling was carried out. Major article databases and search engines include Google Scholar, Science Direct, Web of Knowledge, and Scopus. The focus was on publications within the recent years with current developments. Results obtained from Scopus are presented in [Fig. 4](#). It shows that there is an increase in research on recycling of composite materials, which rose from 2000 to the current date. In the context of this encyclopedia, we will examine some issues on recycling fiber reinforced polymer (rFRP) composites based on certain popular questions on the subject. These questions will be answered within the body of this article: Can FRP composites be recycled? Why is it difficult to recycle many composite materials like FRP composites? Can epoxy composites be made 100% recyclable? What is the difference between FRP and fiberglass? How can plastics reinforced with carbon fiber be recycled? Is it more environmentally sustainable recycling than producing virgin carbon fibers? Can carbon fibers recycled from aircraft (or from aircraft and automotive waste) mechanically replace most of the carbon fibers presently used in the industrial, recreational, and sports sectors, given that recycling can be accomplished cost-effectively and that recycled fibers will not be used by the aeronautical sector? What is the role of FRP composites in sustainability? What are the economic and environmental benefits of reinforced FRP composites? What are the waste volumes of FRP composites that can be recycled? What are the best methods to collect and recycle these FRP composites? Are there safety and health concerns in saving cost during the recycling of FRP composites? What are the major applications of recycled FRP composites? What are the major issues facing the science of recycled FRP composites?

Global Market on Composite Materials

The increase in the use of composites – particularly recycled composites – has led to more developments in the application of recycled FRP composites. The market for composite products globally is anticipated to achieve an estimated \$40.2 billion by 2024 and from 2019 to 2024 it is anticipated to expand at a compound annual growth rate (CAGR) of 3.3%. It is anticipated that the worldwide market for end product composites will reach an estimated \$114.7 billion by 2024 ([Wood, 2019](#)). There is an increase in the projection for composite market globally including recycled FRP composites. According to another report, the estimated projection is from \$72.58 billion in 2016 to \$115.43 billion by 2022, at a CAGR of 8.13% from the year 2017 to the year 2022 ([Markets and Markets, 2017](#)). This implies that application of different sectors is increasing by harnessing the properties of recycled composites. These properties include increased building capacity, reduced weight, increased sustainability, and increased strength capability. This projection stated was from a survey carried out with most of the top leading composite companies: Victrex (UK), Gurit (Switzerland), SGL Group (Germany), Solvay (Belgium), Hexcel Corporation (U.S.), Owens Corning (U.S.), Toray Industries, Inc. (Japan), Teijin Limited (Japan), etc., against that of different secondary sources, such as such as Factiva, Hoovers, Manta, etc. [Fig. 5](#) shows the use of composites in the following sectors: Automobiles, aerospace, defense, renewable energy, transportation, marine (pipes, risers, and tanks); construction & infrastructure industries. In an earlier publication, the global market forecast was to grow to £75 billion by the year 2015 ([Hinton, 2017](#)).

However, there is a global challenge to bring down greenhouse gas emissions, reduce dependence on fossil fuels, and increase the use of renewable materials. To this end there is a challenge with using composites, considering that EOL management of composites, particularly the disposal and recycling pathways have not been extensively uncovered. According to the Composites Industry Market report, around 1.141 million tons of composite materials for GFRP were produced in Europe in 2018 ([Witten et al., 2018](#)). In the United States, demand for FRP was expected to increase to nearly

2 million tons in 2017 as shown in **Table 1** (Holmes, 2019). In another report by Freedonia (2017), US demand for composites of FRP is projected to increase by 4.7% annually to 4.3 billion pounds in 2017, estimated at nearly \$23 billion, and will increase to 3.9 billion pounds in 2020 at an annual rate of 3.1%. Presently, the demand finally has recovered from the mild decreases encountered during the recession-impacted era 2007–2012, when possibilities were limited by a sharp decline in building activity, decreased output of motor vehicles, and decline in production of FRP boats, yachts, and recreational small ships. **Fig. 5** shows the UK market opportunity as potentially having growth. In composite part production, it potentially increased. According to a study by Lucintel LLC, there is an increase in the global market for composite products and this is expected to reach \$96 billion by the year 2020, following an increase of 40% as seen from the year 2014 as shown in **Figs. 6** and **7**. The case study of the UK Composite Market shows that there are opportunities available in UK for composites, particularly the recycled FRP composites.

In another study, it was revealed that the annual output of GFRP was approximately 55,000 t in the United Kingdom alone, with an anticipated annual manufacturing increase of 10% in 2010 (Yazdanbakhsh and Bank, 2014). Most of the production and EOL waste in the UK is landfilled, and up to 90% of the GFRP waste is landfilled (Brown *et al.*, 2018; Osmani and Asokan, 2010; Yazdanbakhsh and Bank, 2014). Different researches have been carried out using recycled composites and cement. In an attempt to improve quality of building materials, different composite and recycled debris have been introduced into concrete (Li and Kaewunruen, 2019; Ge *et al.*, 2011; Yin *et al.*, 2013).

Characteristics of Recycled Fibre Reinforced Polymer Composites

The characteristic behavior of recycled FRP composites has shown that the main properties of composites are exhibited, as in Fig. 7. Further studies on the and behavior under increasing temperature, and the wave scattering properties as carried out by Yin *et al.* (2013).

Images of composite fibers and composite specimens with beetroot taken under the SEM show the characterization of the fibers (Hasan *et al.*, 2019) and could be used in bioengineering the recycled composites and biocomposites, as presented in Figs. 8 and 9.

Review on Recycling Pathways and Technologies

Due to the advantages of FRP recycling, it is pertinent to identify recycling pathways for recycling composites. Fig. 10 is used to show the steps that are undertaken in carbon fiber recycling. From collection to combustion with the resin all involves some energy and depends on the type of recycling process considered. A flow chart of a polymer composite waste management process is

Fig. 10 Steps (a)–(i) involved in the carbon fiber recycling process. Courtesy: ELG Carbon Fibre, 2017. Why Recycle Steel? Coseley, West Midlands, UK. Available at: <https://www.recycle-more.co.uk/why-recycle/why-recycle-steel->.

presented in **Fig. 11**. It was developed using the concept by [Rebeiz and Craft \(1995\)](#) on plastic waste management. Energy can actually be saved through recycling. Different researches on the recycling pathways have been carried out on FRP composites ([Yang et al., 2012](#); [Vo Dong et al., 2015, 2018](#)), however the crunch of it requires funding support, collaborations, and monetization of the recycling concepts.

Issues on Commercializing Recycled Fibre Reinforced Polymer

There have been different projects carried out globally on recycling FRP. Reports have also been presented on different viable options and techniques used in recycling, reclaiming, and reusing the recycled fiber reinforced carbon fibers in different products. Despite these breakthroughs, there are challenges facing these rFRP composites. Bringing both these recycling processes and the recycled products to the composite market has been difficult. **Fig. 12** shows the economic advantage of recycled composites from materials to products. During the economic recession in 2009, there was a big hit on many manufacturers, particularly in the composites industry. Due to the economic downturn that occurred, most of these manufacturers now try to keep their companies by just simply having business survival and less on sustainability. However, over these past 10 years, there has been a shift of interest to sustainability and the use of recycled materials in the composites industry and other industries. There is also an increase into the growth phase and the attention to recycling has been heated up.

To overcome these challenges, there is need to carry out more extensive tests that are economically costly but will assist in the development of standards for these products to be qualified and accepted as products with the recycled contents. To this end, there are still issues with the waste volumes generated per location, management of the waste volume to ensure there is constant supply of waste, provenance, and the amount of money that these waste will cost and the debate about companies' willingness to pay for these wastes. They are other issues with health and safety of rFRP composites, the most effective waste management system to adopt for recycled fiber reinforced composites, the requirements for waste management licenses, having a comprehensive understanding of the requirements for the health and safety of rFRP composites and the relate new processes involved in the recycling, the time for adoption of these new processes in the composites industry. Despite that all these are time consuming, it is important to get the required investment needed or the right niche company that can use the raw materials and obtain good finished products, although the recycled finished product may have low profit marginally ([Job et al., 2016](#)). There is also the issue of not having enough trained personnel on recycling of composites, as not many composites manufacturers are keen on recycled composites.

Fig. 11 Flow chart of a polymer composite waste management process.

Fig. 12 Economic advantage of recycled composites from materials to products.

GFRP are seen to be recycled in cement kilns, reclaimed from landfills and mechanically recycled. The FRP wastes have economic value in energy recovery. Normally, energy is recovered from the resin, which is the mineral feedstock for cement (from the fibers and fillers). As a result of them been reinforcing fibers, they also determine the magnitude of reclamation or recycling of that will be achieved. To that note, different disposal options will have to be considered. The major disposal routes for reinforced FRP composites are landfills, mechanical recycling, cement kilns, and EfW. With respect to the EU Waste Framework Directive, it is pertinent to state that not all disposal options currently meet the requirements. The EfW incinerator bottom ash does not meet the requirements of recycling with respect to this Directive. However, both the cement kiln and the EfW are considered recycling routes that are also used in energy recovery, because the mineral content can be recycled into clinker and aggregate, respectively (Brown *et al.*, 2018). The cost of disposing the FRP wastes using landfills, cement kilns, and EfW are comparatively around the rate of £140 per t, because the waste management businesses almost have the same charge for the composites wastes, without regard to the route of disposal. In the UK, the capacity of EfW is increasing currently. With respect to this increase, the cost charged on EfW should potentially reduce as older plants have already made returns on investments and covered the capitals costs, maintenance costs, and running costs.

On the other hand, there has also been an increase in the commercialization of recycled CFRP. This increase in progression is actually in an order of magnitude been of more value than glass fiber. In addition, some large aerospace primes encourage carbon fiber recycling initiatives while an equivalent encouragement for GFRP has never been attained. In the UK, carbon fiber recycling using pyrolysis processes was first established by Milled Carbon in the West Midlands, now known as ELG Carbon Fiber since it was purchased by ELG Haniel in 2011. Currently, carbon fiber recycling based on pyrolysis is active in USA, Germany, Italy, and Japan. In the UK, recycling of glass reinforced polymer (GRP) composites is done at a very low scale, which is basically in-house activity production volume (Job *et al.*, 2016). In January 2019, ELG and Boeing formed the first material supply relationship between a carbon fiber recycler and major aircraft original equipment manufacturer. This kind of collaboration means that recycled FRP composites can be deployed in the aviation industry.

Issues on Supply Chain of Recycled Fibre Reinforced Polymer

The global demand for carbon fiber is estimated to more than double to be between 150,000 t and 180,000 t by 2020. With the manufacturing techniques used today, there is approximately 30% of the overall demand for carbon fiber becoming waste both during the conversion phase and component manufacturing phase of the recyclates. The remaining fiber is added into the finished parts, which will be disposed of later at the EOL. With the increase in the application of CFRP composites in components with shorter service lives, the EOL will range between 2 and 40 years, depending on the frequency of its usage (ELG Carbon Fibre, 2017). Fig. 13 shows a

Fig. 13 Input-output sketch for the recycling process used to recover polyethylene terephthalate. Source: Ashby, M., Shercliff, H., Cebon, D., 2007. Materials: Engineering, Science, Processing and Design. first ed., Oxford: Butterworth Heinemann.

simplified supply chain diagram for recovery process for plastics and composites, with a case study of PET from plastics. The input-output sketch for the recycling process is used to recover PET, for lower-grade products such as fleece.

The market drivers that determine the best disposal solutions of wastes from FRP composites are the market forces of demand and supply, the increasing cost of landfills, the increase in awareness on circular economy thinking, the markets for recycled products, government policies, and legislations on recycled FRP composites. However, the most important driver on commercial viability of rFRP composites is the breaching of new markets (Brown *et al.*, 2018). With the increase in more composite recyclates, there is also an effect on the existing composite manufacturers, and their sources of raw materials. Currently, automobile manufacturers like BMW and VW are also researching on increasing the use of composites on their cars and also using recycled composites and biocomposites (Das *et al.*, 2016; Bharath and Basavarajappa, 2016; Mohanty *et al.*, 2018). This will also increase the economic viability of rFRP composites in the automobile industry. There is need to create more circular recycling on FRP composites, create higher value recycling routes to explore other areas of the market, and increase more economic exchanges and businesses both within the composites industry and with other industries such as the mainstream aviation industry, automobile industry and construction industry.

There are four main drivers that influence the supply chain of recycling carbon fibers. They are the affordability, security and legislative policies, and environmental responsibility. The economic conversion of both the raw wastes from manufacturing and EOL components into different recycled carbon fiber shapes, forms and component designs is very important. This material product, can then be used technically for different applications, making these lightweight carbon fiber composites less expensive. With respect to the security of the supply chain, the application of recycled carbon fibers controls any supply side capacity risk by bringing in high tonnes of carbon fiber from existing production capacity, thus buffing it up. Legislation plays a very great role, as these policies are what guide the manufacturers and the end-users about the product and its circulation in the market. The need for environmental responsibility cannot be overemphasized. In the automotive industry, EU legislation requires 85% of a vehicle to be recyclable. Carbon fiber waste can be recovered and converted to new products using less than 10% off the energy required to produce the original carbon fiber, fulfilling legislative and sustainability targets (ELG Carbon Fibre, 2017).

Issues on Environmental Aspects of Recycled Fibre Reinforced Polymer

Composite wastes could be an environmental concern too, as well as reinforced FRP composites. They could be fine ground into powder form or solid form in product or sheet material form. Composite wastes are also generated in factories, homes, schools, etc., and in different forms as shown in Fig. 14 (a)–(c). Generally, there are environmental aspects too that should be looked at in recycling of FRP composites. Just like the economic aspects of rFRP composites, the environmental aspects are also driven by same factors that affect the breaching of new markets using viable recycling routes. Environmental aspects of these reinforced FRP composites are dominated by the replaced content of the recyclates, particularly the mechanical strength from the recycling process of the virgin fiber and combusting the resin. This process contributes to energy generation and there is a transformation of energy from combustion using coal as fuel in the process.

In a study carried out in line with ISO 14040 (ISO, 2006) by Brown *et al.* (2018), three case studies were analyzed to represent the typical GFRP composite materials. They are the SMC, the continuous composite sheet, and the infused composite materials. The SMC as is often used in automobile and construction applications, assumed 30%/23%/47% resin/glass fiber/filler. The continuous sheet, as used in rooflights, or hand lay GFRP, is used for a large number of applications and is the largest process by

Fig. 14 Different forms of wastes for recycling (a) metal waste, (b) wood waste, (c) composite waste.

Fig. 15 Energy demand in composite recycling methods. Courtesy: Composites UK.

volume, with comparable constituents, assumed 65% resin, 35% glass fiber (CS/HL). The infused composite materials uses infusion in producing products like wind turbine blades, work boats, and leisure boats, assumed 40% resin, 60% glass fiber.

The environmental aspects of processing reinforced FRP composites are dominated by energy demand. Source of energy is the key factor considered in any manufacturing and recycling processes. In most cases, the main source of power for the energy usage is electricity. During these processes, this takes over greater percentage of the energy footprint. Reduction of energy demand is key in improving sustainability as well as the reduction of collateral damage caused by excessive energy put in by the system.

Issues on Energy Demand Aspects of Recycled Fibre Reinforced Polymer

According to [Brown et al. \(2018\)](#), the energy demand in a mechanical recycling process, for instance, is used to hammer the mill machine or to power the motor of the granulator. However, the power requirement is subject to the type of machinery. Any decrease in the energy demand will be beneficial in improving its sustainability. It can also be beneficial in decreasing the collateral damage due to excessive energy input. From [Fig. 15](#), the composite recycling processes and the corresponding specific energy demand is summarized, as carried out by Composites UK, however there is still need to clarify the issue of the nonequality between the recycling processes with respect to the energy demand. Some studies in the EXHUME project reported the energy demand to be around 0.17–0.27 MJ/kg for the Wittmann ML2201 granulator running at maximum capacity of 150 kg/h and about 0.35 MJ/kg for the Wittmann MAS1 granulator (at 30 kg/h). The Eco-Wolf grinder Model GM-2411-50 and IIT Ltd M300 machine respectively have the energy demand of 0.14 MJ/kg (800 kg/h) and 4.75 MJ/kg (around 29 kg/h). They also reported that prerecycling and postrecycling stages, for instance, shredding and sieving, are not as energy intensive as the actual recycling processes. It is noteworthy to state that the specific energy demand for each of the mechanical recycling processes is dependent on the process throughput with the most minimal lowest value when operating at its maximum machine capacity. During this stage of processing, the basic power requirement of the machine drive motors can be maximized with care thereby subsequently reducing the specific energy demand.

Today, pyrolysis and chemical processes exist commercially, as large scale recycling processes available for carbon fiber composites. From a literature review carried out by Composites UK, the average energy demand for a conventional pyrolysis process reported to be within the range of 23–30 MJ/kg but no information on processing scale is included. Microwave pyrolysis is reported as more energy efficient compared with the conventional pyrolysis due to fast and selective heating – With estimated energy demand about 5–10 MJ/kg. Also, organic by-products can be retrieved for energy or chemical feedstock from these processes. However, synthesis and refining steps may escalate the process energy demand even further. Hitachi Chemical (Japan), developed a chemical recycling process for epoxy based tennis racquet with energy demand between 63–91 MJ/kg and maximum processing capacity of 17,000 racquets per month. The solvent dissolution and water distillation steps dominated the process energy footprint. A pilot scale chemical recycling process at the University of Birmingham used a mixture of acetone and water to recycle 300 g of RTM6 CFRP plate. The process took around 3.5 h (0.085 kg/h) and had an electricity energy demand (for heating) around 21 MJ/kg. Optimization and upscaling the process will enable higher processing rate and lower specific energy demand. [Fig. 15](#) shows that the recycling energy demand is relatively lower (10 to 20 times lower) compared with embodied energy of production for virgin glass (13–32 MJ/kg) and carbon (183–286 MJ/kg) fibers. Environmental credits from avoidance of virgin material can be realized through cross sector applications of the recycle (Brown et al., 2018). An instance is using glass fiber thermoset waste in railway products

Fig. 16 Average comparison on embodied energy of fiber production and potential recycling processes. Courtesy: Composites UK.

Fig. 17 Level crossing panels including recycled glass reinforced polymer and phenolic from car parts. Courtesy: Reprocover.

can avoid production of virgin or new concrete material, by Reprocover as shown in Fig. 16. By avoiding production of high embodied energy material (such as fibers or polymer based material), major environmental benefits can be successfully achieved (Fig. 17).

End-of-Life Waste of Reinforced Fiber Reinforced Polymer

Wastes generated from the manufacturing of FRP composite and at the EOL. Currently, an estimated 1600 CFRP production waste and about 100 t of CFRP EOL. There are also an estimated 6200 t of GFRP production waste and 75,000 t of GFRP EOL waste is generated yearly in the UK. In a study by Brown *et al.* (2018), the constituent materials were broken down and it was found that at least 11,000 t of E-glass fiber waste comes from the early stages of the supply chain of FRPs.

^aFor phenolic and vinyl ester resins, a nominal figure of 500 t resin has been assumed in each case, with 50/50 fiber and resin, as volumes are relatively small.

^bPultrusion value allows for imported pultrusions used in UK manufacturing.

^c70% of the epoxy infusion value is for offshore wind blades, much of which has recently started in manufacturing.

^dBMC EOL factor increased to allow for imported BMC parts.

Abbreviations: EOL, end of life; FRs, fibre resins; GFRP, glass fibre reinforced polymer; UPR, unsaturated polyester resin.

Note: % resin, fiber, filler are by mass. Blue rows indicated calculated values. The estimated data is anecdotal, based on interviews with experienced industry professionals.

Fig. 18 and **Table 2** show the constituents and the estimated quantities of GFRP wastes generated in the UK, as recorded in Brown *et al.* (2018).

With the increase in the application of renewable energy, wind turbine blade waste has a high tendency to increase to over 10,000 t per year in 2030, except for challenges in the lifting, relifting, and hoisting of wind farms. In addition, there is the tendency for the value of recycled CFRP that is recycled through sylvolysis and pyrolysis to increase. An example is the simplified input–output diagram for the recycling of plastics to recover PET, for lower-grade products such as fleece. Thus, this will enable a corresponding increase in the amount of tonnes of aircraft CFRP EOL waste by the year 2030. For FRP wastes, they also have potential application to replace aggregates present in cementitious materials using fillers, but by partially replacing them (Yazdanbakhsh and Bank, 2014).

Application of Recycled Fiber Reinforced Polymer Composites

Due to the different environmental conditions for the applications of recycled FRP composites, their manufacturing and testing are slightly different. However, they make up a great number of applications in use today. The current usage of composite materials is highly driven by the aerospace, marine, and automobile industries. As can be seen in **Fig. 19**, the large proportion of the airplanes are made up of composite materials. In **Fig. 20**, composite materials are used in making automobiles. The parts of cars are made up of different materials like metals, alloys, steels, and composites. With the increase in the researches on recycled composites, recycled fiber reinforced composites are next to be seen on airplanes and on cars. There is limitation on the offshore application on large scale for recycled composites. Offshore structures like cylindrical floating production storage and offloading, paired column semisubmersibles (Odijie and Ye, 2015; Odijie, 2016; Odijie *et al.*, 2017a,b; Odijie, 2015), submarine hoses (Amaechi *et al.*, 2019b,c), composite risers (Amaechi *et al.*, 2019a; Amaechi and Ye, 2017; Gillett, 2018), and other structures require extensive design and material checks. Composites have been an enabling technology in the offshore industry, as seen in wind turbine blades and oil wells with deeper risers. However, while the standards allow small boats, leisure boats, and work boats to be built using composites, the International Maritime Organization Safety of Life at Sea regulations restrict the use of composites and greatly prohibit the structural use of composites due to reasons like combustibility (Job, 2015, 2014).

In the automobile industry, one of the objectives is to have fuel-efficient cars and also lightweight cars. Application of CFRP in car parts reduces the weight of the 30% of a standard car. In another study, it was observed that GRP waste fibers can be used to strengthen the bending in architectural cladding panels and also reduce the propagation of cracks with the cement composites, as

shown in Fig. 21.

In another report by Job *et al.* (2016), the work on continuous FRTP or long FRTP is limited, but more work has been carried out using the thermoset resins. In contrast, the thermoplastic resins are reprocessed and remelted for reuse as recycled FRP composites (Pimenta and Pinho, 2011; Rebeiz and Craft, 1995; Moothoo *et al.*, 2017; Leblanc *et al.*, 2015). There are glass fiber reinforced thermoplastics that have been recycled from automobile wastes and reprocessed into new compounds. On the other hand, the glass fiber reinforced thermoset resins could be degraded thermochemically, thereby helping to recover the organic atoms with low molecular weights.

Job *et al.* (2016) stated that the properly prepared and smoothened carbon fiber reinforced PEEK molded and then injected into virgin PEEK resin and pressed up to 50 wt%, producing recycled composites with mechanical characteristics. There was also the direct recycling process without grinding was also successfully performed but has not applied to EOL composite materials. It is noteworthy that thermoset resins are highly durable, can survive high temperature and have excellent mechanical behavior. However, they can be replaced by thermoplastic resins. Some commercially available thermoset epoxy resins are easier to recycle, as developed by Connora Technologies and Adesso. These thermoset composite resins can be decomposed chemically under low temperature conditions to free up the fiber molecules, and degraded resins that can be used as recycled thermoplastics and as adhesives. Using lignin, recycled composites can also be printed using 3D printing, as shown in Fig. 21. Sustainable 3D-printed products are made from 40 to 60 wt % lignin containing polymeric materials formulated by a solvent-free process and exhibiting appropriate processability constrained by an optimum window of temperature, shear rate and/or filament feeding rate, and viscosity (Graichen *et al.*, 2017; Nguyen *et al.*, 2018) (Fig. 22; Table 3).

Conclusion

There are more economic aspects to be achieved from the recycling of FRP composites. As discussed here, state-of-the-art applications of composites in different industries show a growing demand for composites, and thus the need increases too. The trend in recycling also increases and will be beneficial in the near future based on the current recycling processes and regulations to support recycling in the composite industry. Despite challenges with the application of recycled FRP composites, due to strength issues not highly validated in large scale structures, it is still an enabling technology in some products and can be harnessed. Application of recycled FRP composites in large scale in offshore and marine applications will be one of the key challenges. Economically, it will be successful with small-scale production like remotely operated vehicle handles but will have issues with vibration requirements. Considering the different environmental conditions for oil explorations, such as those that may be harsh, benign, or squall, will also be an issue. There can be more optimization of the impacts by reclaiming fibers very well for reuse as recycled FRP composites and using the leftover resin powder in cement kilns to replace coal, with a large scale, centralized operation to reduce energy impacts. However, technical and logistical advances would be needed before a business model to support this could be proven in a circular economy.

Introduction

The greenhouse gas emissions (CO_2 , NO_x , SO_x , etc.) associated to the manufacture of commercial cements are undeniably one of the most serious problems of the cement industry, whose contribution to the global CO_2 emissions amounts to 5%–7%. The use of supplementary cementitious materials (e.g., fly ash, silica fume, blast furnace slag and natural pozzolans) as a partial replacement of Portland clinker has been improving the sustainability of the cement sector for decades and thus, presently, the carbon footprint of the process has been reduced to 800 kg of CO_2 per ton of clinker produced.

The current implementation of a Circular Economy Strategy in the European Union is encouraging the reuse of industrial waste and by-products as secondary raw materials. According to Eurostat, approximately 2500 million tons of wastes are generated in Europe per year, which represents 30% of the global waste production. Moreover, 48% of those wastes are simply being disposed of in landfills, many of which arise from the construction sector (35%) as well as the mining and quarry industry (28%). In this context, new environmental policies are to be applied, which will have a major impact on the socio-economic development of those countries. The incorporation of new recycled cementing materials into future eco-efficient cements will constitute a priority scientific and technical axis for the scientific community, which will substantially improve the sustainability of the cement sector.

The calcined natural pozzolans have been encompassed within the traditional pozzolans for years, having been included in the cement standards of the 1970s and the 1980s (designated by the letter Q). Despite this fact, the current industrial use of calcined natural pozzolans is virtually nil, probably due to the environmental impact resulting from the extraction of the raw materials (kaolinite) and the natural space protection policies. In this sense, the reuse of kaolinite-based waste for the obtaining of recycled metakaolinite, whose behavior and properties are similar to those of natural metakaolinite, can be presented as an appropriate and eco-efficient solution to mitigate the disadvantages usually related to the natural pozzolans. The studies conducted over the last years within this line of research are focused on the reuse of waste from the paper and coal mining industry as well as from the drinking water treatment plants. This kind of by-products are inert by nature and, therefore, they require a previous thermal activation process in order to convert them into highly pozzolanic materials, in which kaolinite is transformed into metakaolinite and organic matter (cellulose, plant debris, etc.) is removed.

In 2017, coal production in Europe amounted to 464 million tons ([European Association for Coal and Lignite, 2017](#)). With approximately 0.4 ton of mining waste generated per ton of produced coal, coal mining waste becomes one of the most abundant kaolinite-based industrial wastes, followed by paper sludge, a by-product of the paper industry in which recycled paper is used as raw material for the obtaining of cellulose and whose waste generation can be estimated at 14 million tons/year in Europe ([Frías et al., 2018a](#)).

The present article covers the main properties of the most widespread kaolinite-based wastes, paper sludge and coal mining waste, as well as their behavior in cement matrices. To this end, the main scientific and technical advances conducted to date are discussed in this work, based on the worldwide studies on this topic (found in the literature) as well as on the research performed by the IETcc-CSIC Material Recycling Group, which possesses a vast experience in this innovative and eco-efficient research line.

Characterization of the Raw Materials and the Activated Products

A literature review reveals that there is a partial disparity between the chemical composition of the two raw wastes under study ([Amouzadeh Omrani and Modarres, 2018](#); [Beltramini et al., 2010](#); [de Azevedo et al., 2018](#); [Frías et al., 2012, 2018b](#); [Li et al., 2016](#); [Mamat et al., 2018](#); [Modarres et al., 2018](#); [Simão et al., 2017](#); [Singh et al., 2018](#); [Vegas et al., 2009](#); [Vigil de la Villa et al., 2007](#); [Wong et al., 2015](#); [Yan and Sagoe-Crentsil, 2012](#)). Paper sludge (PS) is mainly composed of calcium, aluminum and silicon oxide, whereas coal waste (CW) displays a silico-aluminous nature. As can be seen in [Table 1](#), the chemical composition, expressed in terms of simple oxides, shows a substantial fluctuation even among wastes of the same nature, which is especially conspicuous in the case of the main oxides. Such disparity arises from a variety of factors, including the origin of the waste, the mineralogical load (carbonates/kaolinite), the proportion of recycled paper used in the paper mill or the nature of the soil in the coal mine. Attention should be drawn to the high loss on ignition (LOI) values of the raw wastes, which amount up to 75% and 48% for the PS and CW, respectively. This circumstance is attributed to the dehydroxylation processes of the minerals present in the waste (kaolinite, mica or talc), the decarbonation of carbonates and the decomposition of organic matter (plants, cellulose, etc.).

Qualitatively, a wide variety of minerals can be found in PS and CW as a consequence of the heterogeneity of the wastes, especially in the case of coal waste. The variation range of the content of the main crystalline mineralogical phases, determined by means of XRD-Rietveld methodology and obtained from the limited data available in the literature, is shown in [Fig. 1](#)

Table 1 Ranges of chemical composition of the wastes obtained from the literature (wt%)

Oxides	CaO	SiO ₂	Al ₂ O ₃	SO ₃	Fe ₂ O ₃	MgO	MnO	Na ₂ O	TiO ₂	K ₂ O	P ₂ O ₅	LOI
PS	2–79	5–22	7–16	<2	0.4–1	0.1–2.6	<0.3	<0.7	<13.2	<0.3	<1.8	46–75
APS	19–61	8–31	4–37	<9	0.5–2.6	<10.5	<0.4	<1.5	<2	0.4–3.8	<5.3	6–33
CW	<4	25–62	15–27	<1	3–8	<3.3	<0.08	<2.2	<1.1	<3.6	<0.5	9–48
ACW	2–8	52–62	20–30	<0.7	4.6–8.4	<3.5	<0.14	<2.2	<2	<4	<0.3	0.8–11.7

Fig. 1 Mineralogical composition of the raw wastes.

(Frías *et al.*, 2012, 2018a; Taha *et al.*, 2017; Vegas *et al.*, 2009; Vigil de la Villa *et al.*, 2007). It must be noted that the wastes exhibit a kaolinite-based nature, finding kaolinite contents between 14% and 36% in PS and up to 27% in CW. Quartz, calcite, talc and muscovite are the remaining crystalline phases found in paper sludge, whereas minerals such as quartz, calcite, mica, illite or chlorite have been detected in coal mining waste. In addition, Civeira *et al.* (2016) found substantial amounts of alunite, jarosite, gypsum and pyrite in the particular case of burning coal cleaning rejects.

The nature and crystalline mineralogy of these raw materials prevent them from reacting with the lime available in their surroundings. Therefore, in order to become supplementary cementitious materials, the wastes must undergo a thermal activation process, which mainly involves the complete transformation of kaolinite into metakaolinite (a highly reactive standardized pozzolan) and the removal of organic matter. According to Fig. 2, different activation conditions (furnace temperature and retention time) can be encountered in the literature (Amouzadeh Omrani and Modarres, 2018; Beltramini *et al.*, 2010; Dong *et al.*, 2015; Frías *et al.*, 2012; García Giménez *et al.*, 2016; Li *et al.*, 2006; Modarres *et al.*, 2018; Pera and Amrouz, 1998; Vegas *et al.*, 2009; Vigil de la Villa *et al.*, 2007). In general, there is a consensus on the fact that the optimal activation conditions are a temperature range of 600–700°C and a retention time of two hours since higher values would negatively affect the reactivity of the material due to the agglomeration of particles, which reduces their specific surface, and the recrystallization of metakaolinite.

Fig. 3 shows that the aspect of the raw wastes experiments a significant change after being subjected to the activation process. Both the activated paper sludge (APS) and the activated coal waste (ACW) exhibit lighter colors, as a consequence of the removal of residual organic matter and unburned coal. The chemical composition of the activated wastes, listed in Table 1, does not suffer from major changes, although lower LOI values can be found, as expected, since a significant proportion of the materials susceptible to dehydroxylation or decomposition are transformed during thermal activation.

Pozzolanic Activity of the Calcined Products

Different methods (direct and indirect) have been used for decades to evaluate the pozzolanic character of active additions. The IETcc-CSIC Material Recycling Group has an extensive experience in the use of an accelerated chemical methodology in pozzolan/lime systems, which allows the determination of the amount of fixed lime at different reaction times (García *et al.*, 2008).

Fig. 4 plots the fixed lime contents (expressed in percentage terms) of the activated paper sludge (APS) and the activated coal waste (ACW) after being treated at 600°C for two hours, up to 90 days of reaction. In addition, the fixed lime values determined for three supplementary cementitious materials traditionally employed in the manufacture of commercial cements have been displayed: silica fume (SF), fly ash (FA) and natural metakaolinite (MK). As can be seen from the figure, both metakaolinite-based

Fig. 2 Activation conditions of the wastes tested by different authors.

Fig. 3 Visual aspect of the raw and calcined wastes under study.

Fig. 4 Pozzolanic activity of different wastes employed as supplementary cementitious materials.

wastes show a high pozzolanic activity, fixing ~40% of the available lime at 1 day of reaction, and reaching values of approximately 90% after 90 days. It must be highlighted that the obtained results are similar to those exhibited by the 100% natural metakaolinite. With respect to the standardized pozzolans, the behavior of APS and ACW falls between that of SF and FA, displaying lower reaction rates than SF during the first 7 days of reaction and noticeably higher values than that of FA up to 28 days. Nevertheless, by the end of the experiment (90 days), the fixed lime values are very similar in all the cases under study, which amount to approximately 80%–90% of the available lime.

Fig. 5 Morphology of C–S–H gels and LDH compounds (left) and tetracalcium aluminate hydrate (right) found after 28 days of reaction in a ACW/lime system.

Table 2 Ranges of variation of the rheological properties of the blended cement matrices expressed in percentage terms with respect to a reference cement matrix (assigned value of 100%)

	APS content (%)					ACW content (%)				
	2.5	5	10	15	20	6	10	20	30	50
Flow	68	54–88	43–73	32–62	18–66	91	88–95	80–95	113 ^a	130 ^a
IST	–	115–156	76–242	255–297	77–359	77–97	77–103	71–116	104	85
FST	–	135–156	91–233	254–344	84–465	78–95	78–105	63–107	91	76

^aValues corresponding to the amount of water required to obtain consistencies comparable to those of the reference mortar.

Nota: Frías, M., Vigil de la Villa, R., García, R., *et al.*, 2018b. Effect of a high content in activated carbon waste on low clinker cement microstructure and properties. *Constr. Build. Mater.* 184, 11–19

According to previous research (Frías *et al.*, 2008; García *et al.*, 2015), the pozzolanic reaction studied in the pozzolan/lime system gives rise to the formation of qualitatively similar hydrated phases. Nevertheless, the concentration of those phases and their evolution with time depends on factors such as the activation conditions, the metakaolinite content or the presence of other mineralogical phases on the industrial waste (sulfates, carbonates, etc.). Overall, both APS/lime and ACW/lime systems lead to the formation of C–S–H gels, stratlingite (C_2ASH_8), tetracalcium aluminate hydrate (C_4AH_{13}) and Layered Double Hydroxides compounds (LDH). Additional hydrated phases were identified, such as monosulfoaluminate hydrate (in ACW) or thomsonite and/or chabazite-type zeolites (in APS). By way of illustration, Fig. 5 shows the morphology of some of the aforementioned compounds observed after 28 days of reaction in the ACW/lime system.

In a pozzolan/cement system, the process is more complex and the presence of other oxides as well as the pozzolan content can affect the reaction rate and the formation of the hydrated phases resulting from the pozzolanic reaction. This circumstance arises as a consequence of the existing dependency situation between the hydration rate of the anhydrous cement particles and the pozzolanic reaction, which is limited by the amount of available lime in the system.

In light of the above, the outcome of the pozzolanic reaction in a blended cement matrix varies substantially from that obtained in a pure pozzolan/lime system. The presence of ACW in a blended cement promotes the formation of C–S–H gels, tetracalcium aluminate carbonate hydrate (C_4ACH_{12}) and C_4AH_{13} , whereas the addition of APS mainly favors C–S–H gels and C_4AH_{13} as hydrated phases (Frías *et al.*, 2016; Vigil de la Villa *et al.*, 2010). It must be highlighted that the presence and amount of these phases will have a direct impact on the properties of the new eco-efficient cements.

Rheological Properties

Table 2 shows the variation ranges of some rheological properties of blended cements prepared with different amounts of APS (Ferrándiz-Mas *et al.*, 2014; Ferreira *et al.*, 2013; García *et al.*, 2008; Malaiskienne *et al.*, 2018; Yan *et al.*, 2011) and ACW (Beltramini *et al.*, 2010; Frías *et al.*, 2018b; Modarres *et al.*, 2018; Vegas *et al.*, 2015), including the slump of the standardized blended cement mortar on the flow table and the initial and final setting times (IST and FST, respectively). The values displayed in the table are expressed as relative percentages with respect to the values exhibited by a reference ordinary Portland cement matrix, which has an assigned value of 100%. Therefore, quantities over 100% imply higher slumps or setting times than those of the reference cement (mortars or pastes, respectively) and, consequently, those below 100% indicate lower values with respect to the reference.

Fig. 6 Relative compressive strength at 28 days of APS blended mortars (left) and ACW blended mortars (right).

In light of the results gathered in the table, it is clear that there exists a wide variation in the rheological properties for both pozzolans, primarily due to the great chemical and mineralogical heterogeneity of the starting materials.

In general, the blended cement mortars prepared with these metakaolinite-based pozzolans at a fixed water/binder ratio present lower slump values with increasing levels of replacement, especially in the case of APS. Conversely, ACW mortars show moderate reductions in the slump test, that amounts up to 20% for a 20% level of replacement. Slump values are not available in the specific cases of 30% and 50% substitution levels and therefore, the table shows the amount of water necessary to obtain similar consistencies with respect to the reference mortar. Thus, it can be seen that water demand increases by 13% and 30% for blended mortars containing 30% and 50% of ACW, respectively.

Regarding the setting times, it can be observed that, in spite of the wide dispersion of values, there are substantial differences in the behavior of APS and ACW blended cements. A clear trend cannot be distinguished with respect to the influence of the addition of increasing amounts of APS, which can have both an accelerating and a retarding effect on the setting times with respect to the reference paste. On the other hand, ACW has a general accelerating impact on the pastes, which show values below to those of the reference paste in most of the cases.

The variation found in the literature with respect to the behavior of both the APS and ACW blended cements reveals the existence of different factors that can have a significant impact on the rheological properties of the material: the nature of the waste, the water/binder ratio employed in the preparation of the paste or mortar, the conditions of the activation process, the amount of pozzolan added to the blend, the presence of minority elements (Zn, Pb, etc.), the existence of coal remains or unburned matter, the fineness of the pozzolan, the presence of cellulose, etc. These considerations are in line with the results reported by [Modarres et al. \(2018\)](#), in which the setting of blended cements containing low substitution levels of pozzolan was accelerated due to the filler effect, whereas a retarding effect was found in those cements prepared with higher pozzolan contents as a consequence of the low cement content.

Compressive Strength

The relative compressive strength values of APS and ACW blended mortars, with respect to a reference ordinary Portland cement, measured after 28 days of hydration by different authors, are shown in [Fig. 6](#). For comparative purposes, only the results obtained after a curing time of 28 days have been plotted, as that is the age considered as a reference in the current standards for commercial cements. The literature includes several examples of compressive strength tests performed on both APS ([Ferrándiz-Mas et al., 2014](#); [Ferreiro et al., 2013](#); [Malaikiene et al., 2018](#); [Yan et al., 2011](#)) and ACW ([Beltramini et al., 2010](#); [Vegas et al., 2015](#)) blended cements with substitution levels up to 20%. Nevertheless, only one author reports the results of low-clinker cements, containing up to 50% of ACW ([Frías et al., 2018b](#)).

The evolution of compressive strength in APS blended mortars follows two different trends. Firstly, those mortars prepared with a water/binder ratio of 0.5–0.6 display mechanical properties similar to those of the reference mortar. On the other hand, the authors employing higher water/binder ratios (0.7–0.8) have reported major losses in the mechanical performance of the blended mortars, whose values exceed the replacement percentages of pozzolan.

The behavior of ACW blended mortars does not significantly differ from that of APS blended mortars when the pozzolan is added up to a 20% substitution level, showing compressive strength values comparable to those of the reference. In contrast with the previous cases, the studies performed by [Frías et al. \(2018b\)](#) and [Vegas et al. \(2015\)](#) on 20% to 50% ACW blended mortars, which include the use of a water-reducing admixture to maintain a constant water/binder ratio of 0.5, reveal an important loss in compressive strength. This circumstance relates, among others, to the excess of pozzolan with respect to the available portlandite content, the low cement content and the presence of air voids. Nevertheless, a refinement process of the microstructure was

detected in the blended mortars by the authors (Frías *et al.*, 2018b), which was attributed to the development of nucleation points for the formation of the cement hydrated phases.

Conclusions

The Circular Economy Strategy considers the reuse of industrial wastes as secondary raw materials as a priority line of action for the socio-economic development of a country.

The research conducted in the continuous search for future eco-efficient pozzolans that can be used as alternative additions to those traditionally used in the manufacture of commercial cements (silica fume, fly ash, natural pozzolans, slags, etc.) is instrumental in increasing the sustainability of the cement sector. In this context, the exploitation of kaolinite-based wastes for the production of recycled metakaolinite is becoming a subject of special interest in the scientific community.

On the basis of the findings set out in the present work, the optimal conditions for the activation of paper sludge and coal mining waste, from a scientific, technical, energy, economic and environmental standpoint, are a temperature between 600°C and 700°C and a retention time of 2 h.

Being a relatively new research line, important scientific and technical gaps can still be found regarding the properties of these kaolinite-based wastes. Consequently, the results found in the literature might appear to be inconsistent, even for the same type of waste. This circumstance is mainly motivated by a set of factors that are directly related to the nature, composition and reactivity of the waste as well as to other variables such as the activation conditions, the water/binder ratio, the substitution levels, etc. Nevertheless, the findings exposed in the present work reveal the viability of these two metakaolinite-based wastes, activated paper sludge (APS) and activated coal mining waste (ACW), as raw materials for the manufacture of future low-CO₂ cements, as they have proven to possess comparable properties to those of pure, natural metakaolinite.

In spite of this, it is still of paramount importance to enhance the scientific knowledge in this subject, particularly in those aspects related to the establishment of global action protocols for the activation process of the pozzolans, the study of the durability of the blended cements against aggressive media (CO₂, chloride and sulfate ions, seawater, freeze-thaw cycles, etc.), the assessment of the behavior of these wastes in concrete matrices and, finally, we must not forget the importance of the incorporation of these new eco-efficient pozzolans in the current standards that regulate the manufacture of sustainable cement and concrete.

Influential Parameters on Formation of PEMs on Recycled Fibers: A Review

Hamidreza Rudi, Shahid Beheshti University, Mazandaran, Iran

© 2020 Elsevier Inc. All rights reserved.

Introduction

Recycled paper, as a huge source of cellulosic fibers, has been regarded as a secondary base for preparing raw material in pulp and paper industry. In some countries, accidentally, paper making industry accounts for the main consumer of recycled paper and any shortage for supplying these types of raw materials can affect production delays, and upset manufacture. Nevertheless, it is recognized that the cellulosic recycled fibers have inferior quality and strength properties compared to virgin cellulose fibers (Hubbe and Heitmann, 2007). Accordingly, most of recycled papers have been applied as fibrous raw materials for manufacturing of low-quality grade papers and paperboards. This would include newspapers, toilet roll, corrugating board and test liner, for example, in Europe and Asia. Therefore, the use of recycled fibers for making higher paper grades such as printing and writing papers is still at low level. The reasons for lower quality of recycled fibers are partly attributable to the some events took placed in the fiber structure during paper sheet forming and drying processes, including hornification phenomena (Weise *et al.*, 1998; Billosta *et al.*, 2006; Hamzeh *et al.*, 2012) and polysaccharide hardening (Atalla, 1997). Furthermore, it is generally believed that these phenomena are particularly associated with the formation of irreversible or partially reversible hydrogen jointing in pulp fibers upon drying process considered as what happened for some of the recycled fibers. Consequently, these impact will change the main characteristics of recycled fibers, including fiber strength, fiber length, fiber swelling, and jointing potential of the fibers, leading to a reduction in the strength properties of the resultant papers (Ellis and Sendlachek, 1993). Taking into consideration the fact that the quality of recycled pulp fibers depends also on how many times the secondary fibers have been experienced the cycle of fiber recycling, which intensify negative effect of recycling on the fibers characteristics and diminish suitability of these fibers for preparing market acceptability rate of paper products.

Several attempts have been made to improve the jointing ability and quality of recycled fibers for papermaking. According to the literature consulted, beating and refining, chemical additives, blending with virgin fibers, and fiber fractionation are the most frequently research and industry-led efforts to overwhelm the problems associated with the strength and quality inferiority in the recycled fibers. Refining/beating, despite of being capital- and energy-intensive operation, is the most frequently used method for improving of jointing potential in both virgin and recycled fibers (Wistara and Young, 1999). Though the inter-fiber jointing potential and strength properties of paper can be substantially improved by refining treatment of the fibers (Seth *et al.* 1979), but it also tends to generate fiber fines, decreases greatly the rate at which water can be removed from the wet web of paper sheet, finally limiting the rate production of paper (Bhardwaj *et al.*, 2004; Hubbe *et al.*, 2006, 2007). Refining action also tends to reduce the capability of the fibers to form strong inter-fiber joints when the recovered paper is consecutively made into recycled paper (Pycraft and Howarth, 1980; Weise, 1998).

Additionally, application of chemical additives such as starch derivatives which are already used in papermaking industry as dry strength agent can be considered as another alternative for modifying the jointing capability of recycled fibers (Rudi *et al.*, 2019). By this means, these bio-chemicals have attracted a lot of consideration in papermaking section since they are not only non-toxic and biodegradable but also very cost-efficient due to their low price since they are abundant and available. Practically, starch is modified to the cationic form to adsorb electrostatically onto the negatively charged cellulose fibers. The adsorbed cationic starch increases the adhesive interaction between the fibers, leading to an increase in the paper strength. In one hand, applying starch strength-enhancing agent the strength development of paper products relies heavily on the amount of absorbed cationic starch on the surface of cellulosic fibers (Wågberg *et al.*, 2002). In the other hand, the absorption rate of cationic polymers on the anionic cellulosic fibers depends remarkably on electrochemical property or surface charge, the so-called zeta potential (ζ -potential) of fibers. In other word, the higher zeta potential means larger accessibility of functional groups, imparted the surface for larger potential of absorption of strength-enhancing materials, consequently resulted in paper sheet with higher strength properties (Blomstedt, 2007; Torgnysdotter *et al.*, 2007). In case of recycled fibers, the important practical implication of this method is that it might be possible to improve the strength properties of recycled pulps samples by controlled introduction of functional groups into pulp fibers.

Based on previous published reports, polyelectrolyte multilayering (PEMs) treatment through layer-by-layer (LbL) technique, as a new way in nanotechnology, can be applied to modify the electrochemical properties of fibers (Eriksson, 2006; Ryu *et al.*, 2009). Generally, PEMs is performed by treating a charged substrate such as cellulosic fibers with oppositely charged polyelectrolytes, with intermediate rinsing step (Carosio *et al.*, 2013; Hernandez-Montelongo *et al.*, 2017). The successful charge gain after every deposition step allowed a continuous cycling of the procedure for hundreds of layers (Chin *et al.*, 2012; Dewald and Fery, 2017), which imparted a larger potential to the fibers surface for the higher absorption of target materials. Therefore, this study was intended to evaluate the formation of starch based PEMs system on the recycled fibers. It was also aimed to explore the impact of pulp pH, electrolyte (salt) content and starch degree of substitution on the variation of zeta potential of the fibers. Finally, the strength gain was investigated in the resultant papers during PEMs treatment.

Material and Methods

Fibers

The recovered papers of old corrugated container (OCC) were selected as a typical sample of recycled fibers which nowadays is widely used in papermaking industry for manufacturing different packaging grade papers. First, the contaminants and non-cellulosic parts of OCC papers were removed by hand. Then, preparation and disintegration of pulp fibers was done following SCAN-C 25:76 standard method. Accordingly, the papers were manually torn into small pieces approximately 25 mm × 25 mm in size and soaked in tap water (conductivity $\sim 217 \pm 8 \mu\text{S}/\text{cm}$) for at least 4 h. Then, the soaked sample (360 g oven dry weight of paper) was disintegrated in 23 L tap water by using laboratory L&W Valley Beater to separate the fibers of OCC papers. To complete the disintegration process, the pulp fibers were therefore screened by using laboratory flat screen Voith Sulzer. It includes a chromed plate slotted sieving mesh with size of about 0.2 mm in wide for removal of fiber bundles and oversize components. Finally, the screened pulp was fractionated according to SCAN-M 6:69 by means of Bauer McNett fiber classifier apparatus equipped by sieve frames with screens of 30, 50, 100 and 200 mesh, to prepare pulp free of fines. The fraction of pulps retained before the wire sieve No. 200 with freeness of about $345 \pm 10 \text{ ml CSF}$, which was measured by L&W CSF tester according to TAPPI T-227 om-99 method, collected and stored in lab refrigerator ($\sim 5^\circ\text{C}$) for using in subsequent experiments.

Chemicals

Cationic and anionic cassava starch was provided by Siam Modified Starch (SMS) Co., Ltd. The cationic starch had been modified with a quaternized ammonium group to a degree of substitution of 1.8, 2.7 and 4.5%. For preparation of cationic starch (CS) solution, based on the supplier instruction, it was evenly dispersed in deionized (DI) water, and heated steadily to reach the temperature of about 95°C under continuous stirring. The cooking process continued for about 30 min more under the same temperature ($\sim 95^\circ\text{C}$). In order to avoid changing of starch concentration through the water evaporation during cooking of starch solution the top of the Erlenmeyer flask containing starch solution was covered by aluminum foiling. Finally, after cooling down of the solution to room temperature, the prepared solution of cationic starch was ready and used for the tests only within 24 h.

The anionic starch (AS) has been modified by oxidation of alcohols groups into the carboxylic acid groups to a DS of about 14.5%. This type of starch was also prepared in accordance with the manufacture's recommendations. Accordingly, the anionic starch was soluble in cold water, and used after complete solubilization by homogenous agitation in cold DI water for about 30 min.

Methods

Fiber Treatment

LbL multilayering of starches was carried out by alternate adsorption of cationic and anionic starch onto the OCC pulp fibers. For each step of treatment, 500 ml fiber suspension containing 3 g dry fibers was used. Dynamic Drainage Jar (DDJ) apparatus (Electro-Craft Motomatic II, Canada) was applied to mix the fiber suspension and the starches solutions. The pulp fibers were firstly treated with cationic starch, 1% based on the OD weight of fibers. After mixing of fiber suspension and cationic starch solution for about 10 min, the sample was properly washed three times on a filter paper No. 4 in a Büchner funnel by using DI water prepared from reverse osmosis (RO) storage tank. Rinsing is quite important as it removes weakly attached, physically adsorbed components, thus preparing the fibers surface for subsequent adsorption [Lvov, 18]. At the next step of experiment, the washed pulp was consecutively treated by anionic starch with the addition of 1% based on the OD weight of fibers, and washed again by the same way as explained above. This assembles 1 bi-layer of starch polyelectrolytes on the fiber surface. The experiments were conducted to build up to 8 consecutive layers. Fig. 1 represents a schematic procedure of polyelectrolytes multilayering used

Fig. 1 A schematic illustration for layer-by-layer technique to fabricate two layers of polyelectrolyte on the negative charged OCC fibers surface (The procedure may be repeated to assemble higher number of layers on the fibers).

Table 1 Variables of current study

Parameter	Unit	Value
pH	–	5, 7 and 10
Salt concentration	M NaCl	0.001, 0.01 and 0.1
DS of cationic starch	%	1.8, 2.7 and 4.5
Number of number	–	1 to 8

**Fig. 2** Zeta potential changes of recycled fibers during forming of starch PEMs with different DS. Each value represents the mean of three replicates $\pm$ SD.

in this study. Additionally, to figure out the impact of pH, pulp electrolyte content and starch DS on the variation of zeta potential of the fibers and the tensile strength of the resultant sheets, three pH strategies for pulp suspension (~ 5 , 7, and 10) were adjusted by using 0.5 N HCl and 0.5 N NaOH. Meanwhile, the pulp salt concentration were adjusted to the values of about 0.001, 0.01 and 0.1 M NaCl, which represents pulp electrolyte content to about 140, 1160 and 10,570 $\mu\text{S}/\text{cm}$, respectively. **Table 1** represents the multilayering variables of this study.

Zeta Potential Analysis

Change on the Zeta potential of the treated fibers was measured by using a Mutek SZP-06 system after each step of LbL treatment of OCC fibers. Zeta potential (ζ -potential) of the fibers was detected to examine the charge characteristics of fibers surface and the success of cationic and anionic starch absorption. The procedure was repeated for each layer deposition until the assembly of 8 layers. The ζ -potential experiments were carried out in triplicates and the average $\pm$ standard deviation (SD) values have been represented.

Sheet Preparation and Testing

Handsheets at grammage of about $60 \pm 3 \text{ g}/\text{m}^2$ with $16.5 \text{ cm} \times 16.5 \text{ cm}$ in size were made of both untreated and treated fibers using laboratory handsheet maker. They were pressed at 400 kPa for 5 and 2 min, respectively and dried at 120°C for 2 h. Handsheets were conditioned according to SCAN-P2:75 at constant temperature of $23 \pm 1^\circ\text{C}$ and relative humidity $50 \pm 2\%$ before testing. Tensile index measurement was conducted according to SCAN P-67:93 by means of Tensile Tester, MTS Synergie 200. The system is equipped with 1 kN load cell and controlled by TestWork V.3.09 software. All the experiments were carried out in triplicate to confirm the experimental results, and the average of the values as well as standard deviation were presented, only if the percent relative standard deviation for samples was less than 5%.

Results and Discussion

Effect of Starch DS on Fibers ζ -Potential

The changes in the zeta potential after adsorption of starch layers on OCC recycled fibers as a function of starch DS are shown in **Fig. 2**. Based on the results obtained, the reversion in zeta potential showed the formation of starch PEMs successfully onto the

Fig. 3 Tensile index of sheets made from OCC fibers treated by PEMs with various DS of starch as a function of layer number. Each value represents the mean of three replicates $\pm$ SD.

OCC fibers surface for all starch DS combination used in this investigation. In consistent with previous results, measurement of zeta potential is a standard way to detect the achievement of polyelectrolyte multilayers construction, leading to a clear change of fiber charge after each layer assembly (Xing *et al.*, 2007; Bellanger *et al.*, 2017). Further, the starch DS shows influence on zeta potential of the fibers. The zeta potential for untreated OCC fibers, for example, due to negatively charged groups partially dissolved at the fibers surface detected a net-negative value of about -16.9 ± 4.4 mV. It was reversed to the values of about $+24 \pm 5.1$ mV and $+3.1 \pm 8.2$ mV, when starch with DS of about 1.8% and 4.5% was used, respectively. First, this verified the assembly of the first cationic layer onto the fibers surface. Secondly, by depositing of starch with low DS ($\sim 1.8\%$), the sign of the net charge was higher in the first assembled layer, which shows more effective growth of cationic layer on the fibers surface for the first layer. For the first layering, polyelectrolyte adsorption is largely influenced by the surface properties of the fibers and therefore a higher amount of lower DS starch is required to neutralize the surface charge of the fibers (Laurant and Schlenoff, 1997; Ladam *et al.*, 2000). On the contrary, by assembling of starch with high DS ($\sim 4.5\%$), the sign of the net charge was higher in larger number of layering (5th layer). This implied that higher absorption of starch took place at larger number of layer. This is attributable to the correspondence between charge property of pair polyelectrolytes, i.e., cationic and anionic starch. On other words, higher DS cationic starch accompanied by a greater charge balance with an anionic starch would lead to further adsorption, more stable ionic starch layers and higher zeta potential. This consequences higher affinity of fibers surface for higher absorption of strength-enhancing materials such as cationic starch, which remarkably affects the strength properties of the papers (Hubbe *et al.*, 2005).

The tensile index of sheets prepared from LbL-treated OCC fibers using various DS of starch as a function of layer number is shown in Fig. 3. The results shows improvement of the strength with starch PEMs formation in all DS combinations. The results also indicates that the DS of starch was influent on tensile index of the resulting papers. In accordance with the higher value measured for zeta potential, the tensile index of the sheets improved as a function of the number of adsorbed layers and depended significantly on the DS of the applied cationic starch. Correspondingly, when starch with DS of 1.8% was used, the prepared papers were stronger than those of papers made from the fibers treated with greater DS of starch, particularly in assembling lower number of layers (1st and 3rd). However, on increasing the number of layer assembled on the fibers the tensile index of the sheets increased significantly and the highest tensile index was obtained in the outmost layers (7th layer) using cationic starch with higher DS (DS $\sim 4.5\%$). As previously mentioned, greater charge balance between cationic and anionic starch would lead to more stable layers, therefore resulted in enhancing the tensile strength of the paper sheets.

Generally, recycled fibers treated by PEM deposition of ionic starches exhibited different properties from that of untreated fibers. This fact is confirmed by the different appearance of the surface and the fibers network, indicating the ability of PEM treatment for engineering the fibers surface characteristics. Based on SEM and AFM results in Fig. 4, sequential deposition of the strength-enhancing polyelectrolytes can increase the surface roughness of recycled fibers due to growing adsorption of cationic starch on the fiber surface, which resulted in generating a gel-like appearance on the surface improving inter-fiber ability between the recycled fibers.

Effect of Salt Concentration on ζ -Potential

Pulp conductivity which represents the amount of dissolved salt ions in the aqueous solution of fibers slurry is another important parameter affecting the electrochemical property of fibers and polyelectrolytes. Therefore, zeta potential values of cellulose fibers suspended in water may be profoundly affected by changes in the conductivity of the aqueous medium (Youn *et al.*, 2007) Fig. 5 shows the effect of different conductivities of pulp suspension on zeta potential during LbL treatment of OCC recycled fibers. As can be seen, the measured zeta potential is higher for the suspension free of salt ions (0 M of NaCl) in the first layering of cationic

Fig. 4 SEM and AFM micrographs of the paper sheet surface (10 g m^{-2} basis weight): (a), paper made from the untreated recycled fibers; (b), papers made of the PEM-treated recycled fibers.

Fig. 5 Zeta potential changes of recycled fibers during forming of starch PEMs in different salt concentration. Each value represents the mean of three replicates $\pm$ SD.

starch, where there is possibility to occur both electrostatic and non-electrostatic interaction to absorb starch molecules on the fibers surface (Lundstrom-Hamala *et al.*, 2010). General suggestion is that the solution media, in this case, is the best environment for fiber surface ionization and polymer adsorption both through ionic attraction and a non-ionic interaction such as hydrogen bonding. Additionally, in the following layers, at NaCl concentration of about 0.001 M, especially when the outermost layer is cationic (odd-numbered layer, 5th and 7th layer), zeta potential is higher than those of other levels of conductivities. The output is consistent to the result from Youn *et al.* (2007). They reported that higher zeta potential was obtained when pulp fibers were multilayered at the condition of slightly salt concentration.

Meanwhile, at the electrolyte content of 0 and 0.001 M of NaCl, due to the least negative effect of salt cations, there is a regular variation in zeta potential. However, at 0.001 M of NaCl, the measured zeta potential of the fibers is higher than that of samples without any salt cations, which could be expected for the recycled fibers to absorb greater ratio of starch. In consistent with current findings, earlier reports have demonstrated that effective size or less extended conformation of the polyelectrolyte in fibrous slurry or “coiled-up” conformation of the polyelectrolytes in the aqueous solution (Youn *et al.*, 2007; Ryu *et al.*, 2009) are responsible for increasing polyelectrolytes adsorption. Fig. 6 illustrates a simplified scheme of coiled-up conformation of polyelectrolytes in the salty aqueous solution.

The effect of conductivity during LbL process on tensile index of the papers has been presented in Fig. 7. It is apparent that strength improvement in this system was connected to the number of layer assembled onto the fibers. Expectedly, the tensile value obtained for the first layering was higher when the pulp suspension has no salt ions, 0 M of NaCl. The most acceptable suggestion is that the first layer is controlled both by electrostatic and by non-ionic interactions between fibers and polyelectrolytes (Lundstrom-Hamala *et al.*, 2010). Therefore, the environment without any salt cations results in better situation for non-ionic interactions such as hydrogen bonding between cellulosic fibers and starch molecules. Simultaneously, electrostatic ionic interactions may also take place since a media without salt outcomes a reduction of Debye screening length. However, in the subsequent layering where the electrostatic attraction is only the driving force for adsorption process (Sukhorukov *et al.*, 1998), a low content of conductivity, 0.001 M of NaCl, contributes to the polyelectrolytes more efficient conformation of polyelectrolytes

Fig. 6 The effect of increased conductivity on conformation of cationic starch molecules.

Fig. 7 Tensile index of sheets made from OCC fibers treated by starch PEMs under various conductivities as a function of layer number. Each value represents the mean of three replicates $\pm$ SD.

on the fiber surface as what explained for the variation of zeta potential. In line with current result, Larsson and Wall (1998) demonstrated that adding aluminum salts accompanying with cationic starch improves the system efficiency of starch retention. Furthermore, Ryu *et al.* (2009) reported that at low conductivity because of coiled-up conformation of polyelectrolytes in the aqueous solution, the adsorption ratio was higher. As a result, at low salt concentration of 0.001 M of NaCl, with 140 μ S/cm electrical conductivity, tensile index was remarkably increased. It was improved more than double after five layering compare to the control sample. In addition, the improvement of tensile strength was dependent on the type of outermost layer, i.e., cationic or anionic. For all electrolyte values, tensile strength improved with cationic starch, particularly when 7 layers of polyelectrolytes assembled on the fibers surface. Moreover, at higher salt concentration of about 0.1 M of NaCl, tensile strength decreases significantly. Probable explanation is that the electrostatic attraction between polymer particles and carboxyl groups on the fiber surface is screened and the adsorbed amount decreases (van de Steeg *et al.*, 1993). Another suggestion is that a high conductivity may shrink the effective size of the flocculent polymer and consequently reduces its efficiency (Wang and Hubbe, 2001).

However, in such environment added polyelectrolytes can develop the adhesion between the fibers by developing the molecular contact area and/or the number of effective fiber-to-fiber joints, which result in forming more compacted and dense paper sheets with higher tensile strength, and lower apparent thickness, as depicted in Fig. 8.

Effect of pH on ζ -Potential

Fig. 9 shows the change in zeta potential of recycled fibers during LbL treatment at different pH values. In general, an alternate fluctuation of zeta potential demonstrates the consecutive fabrication of the multilayers of cationic and anionic starch on the surface of recycled fibers in all pH values of pulp suspension. However, the results indicate less change in zeta potential were achieved at acidic pH value (pH $\sim$ 5), due more to the lower dissociation of both carboxylic acid groups on the fibers surface and polyelectrolyte molecules in the fibers suspension. On the contrary, higher zeta potential was achieved at higher pH values of fibrous slurry (pH $\sim$ 7.5 and 10), which lead to obtain more cationized fibers within the following cationic starch layering. This is in consistent with earlier reports (Youn *et al.*, 2007; Ryu *et al.*, 2009). Pulp treatment under alkaline pH conditions affects the ionic character of fibers and additives applied to absorb on fibers surface. There are some reasons with respect to the effect of pH on fibers behavior. One idea is that higher pH of pulp suspension lead to swell the fibers structure for greater accessibility of functional groups which react with additives particles effectively. Another suggestion is that it increases the degree of dissociation

Fig. 8 SEM images of the thickness of paper sheet (60 g m^{-2} basis weight) made from (a) original CMP fibers, (b) untreated recycled CMP fibers, and (c) PEM-treated recycled CMP fibers.

Fig. 9 Zeta potential changes of recycled fibers during forming of starch PEMs in different pH. Each value represents the mean of three replicates $\pm$ SD.

of polymers molecules and the carboxyl groups at the fiber surface, which consequently increases the joints potential between fibers and additives (Wang and Hubbe, 2001; Ryu *et al.*, 2009).

Fig. 10 shows how tensile index of the sheets made of untreated and LbL-treated fibers was changed under the investigated pH of pulp suspension. Tensile strength of paper was determined by two key factors, fiber strength and bonding strength (Page, 1969). Since polyelectrolyte multilayering does not change fiber strength, tensile strength of paper could be regarded as jointing ability between fibers (Ryu *et al.*, 2009). It has been suggested that the starch increases the specific joint strength and the molecular contact area and the number of efficient fiber-fiber joints are possibly also increased (Howard and Richard, 1992). Moreover, the increment in tensile strength with starch addition is largely due to improved specific bond strength and increased stiffness of bonded areas (Ghasemian *et al.*, 2012). However, it has been shown that the strength enhancement is dependent on the amount of starch that can be adsorbed onto the fibers (Wågberg *et al.*, 2002).

The measured tensile index for the untreated sample was about $15.6 \pm 0.7 \text{ N m/g}$. It was significantly increased with polyelectrolyte multilayering of starch at all pH values. The tensile was also depended on the layer number at all pH values. Further, the highest value of tensile strength for the first layer was revealed at pH ~ 10 ($\sim 28.3 \pm 1.5 \text{ N m/g}$). Meanwhile, when the outer layer was anionic,

Fig. 10 Tensile index of sheets made from OCC fibers treated by starch PEMs under various pH as a function of layer number. Each value represents the mean of three replicates $\pm$ SD.

almost in all our experiments, tensile strength has been decreased relative to the previous cationic layer. A good correlation between pH during starch adsorption and the improved tensile strength was also detected. As can be seen in Fig. 8, the development of the strength was higher at pH ~7 and 10 and only minor differences were seen between the results of these two pH values. The maximum increase of tensile index to the value of about 35.1 ± 1.8 N/mg was observed when the outermost layer was cationic for the alkaline condition at pH ~10. This was obtained after constructing of five layers of starch. In other words, this showed a dramatic increase of about 125% in the tensile index compare to the paper made from untreated fibers. These findings are in agreement with previous reports (Wågberg *et al.*, 2002; Eriksson *et al.*, 2005). Generally, the pH value can affect the dissociation of various different types of carboxylic acid and other groups within cellulosic fibers (Lloyd and Horne, 1992; Youn *et al.*, 2007). In addition, it can change the conformation and degree of dissociation of polyelectrolytes in the fibrous suspension (Ryu *et al.*, 2009). It is clear that the fibers and polymers with higher active functional groups result in higher absorption of polymer particles onto the fibers surface. As a result, the resulting papers could be stronger due to the larger jointing potential of the fibers.

Conclusions

In current study, the role of the influential factors, such as starch DS, pH value and salt content of fibrous suspension, on formation of starch PEMs onto the OCC recycled fibers was examined. In PEMs formation, starch with different DS reveals significant influence on zeta potential of the fibers. For the lower number of layering, lower DS starch is more effective to neutralize the surface charge of the fibers, resulted in stronger papers. By contrast, higher DS starch would lead to more stable starch layers, higher zeta potential, and improved papers in larger number of layers. Furthermore, the electrolyte content of the pulp suspension has both positive and negative effect on the zeta potential and strength property of the papers. At lower amount of salt concentration, the zeta potential of fibers was higher, and the prepared paper was stronger than those of papers made from the pulp with higher conductivity. Greater electrolyte content screens the charge of fibers, and deteriorates the paper strength. Meanwhile, zeta potential of recycled fibers was dependent on pH value of pulp slurry during PEMs fabrication. The pH value in alkaline range is believed to further ionize functional groups in cellulosic fibers and starch particles, develops the joint affinity between them, which consequently makes stronger the papers made from recycled fibers.

Introduction

The value that information has received in recent years is incalculable. Until less than a decade ago, storing data seemed far from having a benefit, implying a high cost that in many cases could not be assumed. Advances in computing have made the analysis of information one of the main interests for scientists. These scientists, applying traditional techniques of artificial intelligence in a distributed way, manage to extract in many cases a valuable knowledge that was previously unthinkable (Sanchez *et al.*, 2014; Zygiaris, 2013).

One of the main sources of data generation that can lead to great benefits is the city. The beneficiaries are their citizens. According to numerous studies (Chamoso *et al.*, 2018b), cities can generate large amounts of daily data, spread across a wide range of sectors. The sectors of energy, traffic and public transport, services or public administration are just examples of sectors that can greatly benefit from the analysis of information generated in a city.

Over the last few years, different studies have been carried out to create distributed platforms adapted to recover that information, process it, and put it to the benefit of citizens through different applications. Some well-known examples are the platforms deployed in cities such as Barcelona (Bakici *et al.*, 2013), SmartSantander (Gaur *et al.*, 2015), or Málaga (Carillo-Aparicio *et al.*, 2013). However, there is still no standard that has been taken as a model to follow when deploying a platform that turns a city into a smart city; even within these vertical platforms there are many modules that can be developed from the layer applications such as applications that encourage citizens to carry out beneficial activities for the community.

One of these activities may be to encourage the users of a city to recycle waste. And it is necessary to implement solutions to the problem of what to do with garbage. The vast majority of European countries have adopted measures to recycle this waste (Candanedo *et al.*, 2018; Rivas *et al.*, 2018b).

One of these measures was the creation of urban waste treatment plants to manage the waste generated in the cities. However, for these plants to perform their recycling function it was necessary to develop a waste collection network. In the European Union (EU) there is no common method in waste management. Some countries have deployed a series of colored containers in which the user introduces the waste according to its type; in other countries it is in supermarkets where the consumer is allowed to deliver a series of waste and packaging for recycling. The use of these measures has allowed the recovery of numerous tons of garbage that were previously completely discarded in landfills, obtaining numerous benefits for both humans and the environment.

One of the main disadvantages of these systems is that the recycling of waste is often done altruistically, so it would be interesting to develop a mechanism that encourages this recycling to turn our cities into smart cities. This mechanism can be a module of a smart city platform with those mentioned above or a platform in itself, which can obtain its own data, process it, and make decisions. That is why this article proposes a platform based on agents that take care of all the processes that an Internet of Things (IoT) platform must incorporate to be incorporated in a smart city. The platform of agents thanks to the use of a gamification algorithm performs the task of encouraging users to recycle waste and communicates with the users' mobile application for bidirectional communication processes and that the user knows the state at all times of the achievement of the challenges.

The rest of the paper is organized as follows. The section "Related Work" contains all the works related to this article. The proposed system is shown in the section "Proposed System." The section "Simulation Results" presents the main results of our model and the Conclusion shows the conclusions of our findings.

Related Work

This section reviews the three concepts on which the proposal is based (recycling methods, gamification, and IoT platforms). First, the current methods of recycling in the EU are presented, then the advantages of gamma techniques are shown, and finally the IoT platforms that allow the incorporation of gamma techniques for the encouragement of recycling and how these techniques will help us to increase citizen participation.

Recycling Methods

To prevent large quantities of waste from being deposited in landfills and being converted back into useful materials, it was necessary to develop methods that would allow this waste to be collected separately and structurally so that it could be recycled.

In the EU each country developed different methods to deal with this problem of garbage collection. Spain was the first country to install glass collection containers in 1982. It was in that same year, when a model of cooperation between Autonomous

Communities, local corporations, and manufacturers of glass containers was established for the management of the recycling of this element. In 1994, Directive 94/62/EC dictated the framework on which all the legislation of each of the countries of the European Community was to be developed.

At a general level, two predominant recycling models were developed in the EU within the European legislative framework, in which most of the countries that make up the EU are included. The first model consists of the deployment of colored containers according to the waste for which they are focused. Within this model there are small differences according to each country, such as the color of the container for each package, apart from the containers of urban waste and oil.

However, color identification is not identical in all countries that have adopted this model. For example, in Spain three containers are deployed: Blue (paper and cardboard), yellow (plastic waste), and green (glass). In France, there are three containers: Yellow (paper and cardboard), blue (plastic and aluminum), and green (glass). In Italy the colors also vary with respect to Spain and France. In addition, another variant is when the process of waste collection is carried out, which is governed by an annual planning that sets the days for throwing out the garbage (usually two days a week). The garbage must be deposited the day before the day set in the planning, and in some countries people can receive a fine if they do not recycle. There are even major differences; in Norway the system differs slightly, with one container for organic waste and another for paper and cardboard. The plastic is deposited in special bags, which are placed next to the paper and cardboard container. The glass is placed in special containers next to the supermarkets.

The second method widely adopted in Europe is the Deposit Refund System (DRS), which is being implemented in Germany, Sweden, and Denmark. In this model, in the purchase process the user pays a fee that includes this kind of waste, which is recovered once the container is deposited in perfect condition in the machines intended for collection; the user receives a ticket with which they can get this fee refunded. The DRS is complemented with the colored-container method, as in Germany.

Both methods have a good reputation and acceptance in the countries in which they are deployed, however, both methods have a number of points to review for improvement. The colored container recycling model has one disadvantage: It only allows the collection of some materials and the DRS model only serves to recover plastic or metal containers. Specifically, the DRS only allows the management of 8% of the packages, while, the model of colored containers takes care of 80% of the packages. The operation of the DRS model is linked to machines installed in supermarkets, so that citizens only deposit their packaging at the time when these establishments are open. In addition, in the DRS model the containers are engraved with a tax that the citizen has to pay when buying a product, in case the container presents a flaw or a dent and cannot be recovered.

Both models can therefore be improved, and even benefit from each other's advantages. Recycling by imposition (possibility of being fined) means that this process is carried out with reluctance and without paying attention to the correct recycling in the model of colored containers. The DRS system simply recovers the money that was paid for each container when they were purchased, and a very small percentage of containers are managed by this model.

Gamification to Encourage the Recycling of Garbage

Gambling is a technique that has been developed for incorporation into certain daily activities for their incentive through the use of the mechanisms of play. Gamification arises within the educational sphere. The games are part of a set of activities that promote learning in a playful and interactive way. These games use the typical characteristics of entertainment games to tackle learning tasks, comprehension or social impact, tackling both cognitive and affective dimensions in such a way that they are very interesting for the objectives set out in this proposal. For this purpose, dynamism and gameplay concepts are used that make participation and interaction a stimulus in the learning process.

Gamification uses the characteristics of games with a purpose beyond entertainment and clearly focused on learning. Gaming in the recycling field allows for increased citizen participation in these tasks, allowing rewards to be given to users who perform correct actions according to fixed rules and receiving penalties in the opposite case.

The use of this technique can be focused on increasing the level of participation while maintaining the citizen's commitment to the environment. This technique has recently been used in fields such as home energy efficiency with very satisfactory results ([García et al., 2017a,b](#)). However, it has been detected that it has not been used in the field of recycling so it is interesting to know if this technique produces satisfactory results in this field as well.

Internet of Things Platforms

An IoT platform is the basis for devices to be interconnected and generate their own ecosystem. In other words, a web platform integrated to the IoT is the software that connects hardware, access points, and data networks to what is usually the application the user connects to. The market for IoT platforms is booming and continually expanding; in fact, there are surveys that say that more than 80% of companies believe that the field of the Internet of Things is the most interesting for their businesses. In addition, these platforms are necessary to solve middleware problems.

There is a wide variety of IoT platforms; however, to face the problems we are facing, it is necessary that this platform has a wide capacity to communicate, coordinate, interact and cooperate to carry out different actions. A methodology that combines these characteristics in the development of platforms is the multiagent system (MAS).

These characteristics have allowed this methodology to be applied in works with objectives as varied as the management of drones for livestock monitoring or as a legal control platform for drone flights (Rivas *et al.*, 2018a; Chamoso *et al.*, 2018a), aid in the systems of currency exchange in airports (Chamoso *et al.*, 2019), classification of facial images according to gender and age (González-Briones *et al.*, 2018f), optimization of energy consumption (González-Briones *et al.*, 2018e,b,c,a,d), being in all of them a methodology that has been adapted with high precision to the needs of the problem. It is for this reason that these systems have been widely accepted by the scientific community due to their intrinsic characteristics that allow them to be used in such diverse contexts. They are widely used to model behavior, simulate situations, or solve problems that are difficult or impossible to solve for a monolithic system.

The ability to interact between them without the need for any action on the part of the users gives them their own autonomy that empowers them with the capacity to perceive changes in the environment and react to them, being, therefore, a very propitious methodology for capturing data, learning behavior patterns, and making decisions in the face of changes. The multiagent systems as a basis for the development of an IoT platform allows modeling different architectures based on the above tasks for the development of activities within the field of recycling ranging from behavior simulation, learning behaviors associated with recycling, the efficient management of waste within supply chains, or learning behavioral actions of users.

The agents that make up the platform have their own autonomy that allows them to carry out the aforementioned tasks, making it a very suitable methodology for capturing data, learning behavior patterns, and making decisions in the face of changes. Multiagent systems have been used in different proposals within the field of recycling, from simulating behavior, learning behaviors associated with recycling, the efficient management of waste within supply chains, or learning behavioral actions of users.

For this reason, this methodology has been used in works that meet some of the subobjectives set out in this proposal. One of these works is carried out by Meng *et al.* (2018) in which a platform is presented to carry out simulations of domestic solid waste recycling actions together with the carrying out of social surveys. The agents of the platform simulate different domestic scenarios and based on various decisions simulations are made but does not encourage citizen participation in recycling tasks. In another work such as the one presented by Yang *et al.* (2011) a system is presented for the evaluation of the economic sustainability of a waste recovery system by means of simulation based on agents. To assess economic sustainability, process recycling rate, and economic efficiency, sustainability metrics are used to evaluate and compare two recovery processes.

Another work based on multiagent systems is that carried out by Mishra *et al.* (2012), in which agents coordinate effectively to execute different tasks such as waste categorization, transport, waste recycling, waste management, and assignment of reusable products. The agents allow to carry out a management of all the activities that take place in the supply chain; the management of these complex tasks is carried out in an effective way thanks to the cooperation and communication of the agents that model the supply chain.

These works are a clear demonstration that the agent-based system proposed for the development of an IoT platform to enable efficient management in waste collection chains and collection decision making while encouraging citizen participation in a smart city. The use of multiagent system has shown a number of advantages to simulate this type of problems and learn from the actions taken for decision making.

The development of a platform based on an architecture based on agents that adapts to the needs raised makes it possible to manage independent environments to make more optimized decisions, being able to take these decisions by quadrants, neighborhoods, or regions within a smart city. In addition, thanks to the use of gamma techniques, the platform will reward the neighbors with the greatest participation and will penalize those who do not participate. The platform will have communication with users thanks to the mobile application used by users to measure user participation. As a model for the development of the platform is the one presented by Rodríguez *et al.* (2011), whose contribution is the ability to make dynamic and adaptive plans to distribute tasks among agents (container status, transport management, gamification process, or user management among others). Context-Aware Framework for Collaborative Learning Applications is used for the development of the gamification system as a basis for its technical and social features implementation (García *et al.*, 2015, 2017c). The system learns from the actions taken by users to adapt to them and provide new solutions to increase the recycling rate and citizen participation.

Proposed System

This section details the architecture that has enabled the technical development of the multi-agent system that implements the IoT platform that captures the data and the gamification system for the participation of users.

Infrastructure

Agents of the IoT platform communicate with the mobile application to get information from users. The mobile application captures this information from the infrastructure that needs to be deployed for the case study. This infrastructure should not mean a change in recycling model currently deployed, but a small deployment of sensors that allow data capture. The information that is required by the platform and that must be sent by the mobile application is a structure that contains data related to the quantity, type of waste, the user who performs the action, as well as the state of filling of the containers and degree of occupation of the nearest waste treatment plant.

The infrastructure installed in each container consists of the following devices: (1) a QR code reader enabling the user to be identified. (2) GPS locator, which indicates the coordinates at which the container is located. (3) Weight sensor weighs the amount of waste introduced into the container. (4) Volumetric sensor, it allows to know the state of filling of the container. (5) NarrowBand IOT (NB-IoT) communication technology, for data transmission to the system. NB-IoT technology allows data transmission over long distances. (6) Solar panel, which feeds the different sensors deployed in the container so that the system is independent at the energy level.

The process of interaction between the user, the application, and the platform begins at the moment in which the citizen deposits the waste in a container, then the data structure is generated to be received by the mobile application and then sent to the IoT platform composed of the following fields: User id, type of waste, amount of waste, container id, location of the container, filling status of the container. The data structure is sent via the MQTT protocol using the NB-IoT network to a local station. The local station will act as MQTT broker sending the data in JSON format via REST services. There is a communication line between each container and the waste treatment plant that allows a collection truck to be sent to the containers that are complete (Dijkstra's shortest path algorithm is used to trace this route).

Multiagent Architecture

The architecture is based on agents as this allows to adapt to possible changes such as the growth of the number of containers or change of the location of the containers in the region to be managed. This architecture is therefore dynamic and self-adaptable in real time to the characteristics of the context of the problem.

This process of self-adaptation is determined by the goals, desires, and tasks of each agent (amount of waste to be recycled, percentage of participation, etc.), while taking into account the objectives of the other agents, cooperating among them to achieve the common goal and specific goals. The core of the architecture is a group of deliberative agents who decide autonomously how to act and at what moment to intervene in the collective solution. The functionalities of the agents are not within their structure, but modeled as services. This methodology grants a wide capacity of adaptation to changes and in the recovery of errors. As it has been possible to extract from the review of the state of the art, a multiagent system allows us to adapt to a changing environment such as the increase or change of the location of the containers.

The architecture used is organized in four layers, with the manage layer being the layer in charge of managing the MAS and communicating with the mobile application (Figs. 1–6).

- *Manage Layer.* This layer, made up of at least one agent, is in charge of deploying the rest of the main agents in each layer. This agent also coordinates communication with users through the mobile application to update the progress of each user on the platform.
- *Smart City Layer.* The agents of this layer receive the information from the data structures that are received by manage layer. This layer checks the status of the containers to make decisions if necessary. Big data engine agents analyze the data received by complex event processing for pattern recognition. The architecture has an open data agent to acquire relevant data for analysis, such as meteorological data.
- *Data Layer.* The agents in this layer are in charge of capturing data from the infrastructure deployed in the smart city. IoT agents communicate with the agents deployed in the infrastructure layer to build the data structure that collects the data about the waste deposit in a container, which is sent in JSON format through REST services. The IoT broker performs the NGSI-to-NGSI (Next Generation Services Interface) conversion between IoT agents and the Context Broker agents, and the data is collected by data communication agents who transmit it for analysis to smart city intelligence layer.
- *Smart Government Layer.* This layer manages the results obtained by smart city layer for the collection of waste from containers or a larger deployment of containers in a certain area if the demand for waste collection or a larger shipment of trucks is not met. This layer is responsible for the process and gamification with the user, providing a bonus to or penalizing users with a decrease or increase in the rate of garbage imposed by the local government.
- *Infrastructure Layer.* The agents of this layer act as middleware between the users and the multiagent system. Each container has an associated agent that is responsible for generating a data structure (amount, type of waste deposited, user recycling, filling status of the container, occupancy rate of the nearest waste treatment plant). These agents, using LPWAN, send the information to the data layer agents.

The mobile application is a simple application developed in Android that manages the profile of users, updating the achievements of each user and showing the achievements or penalties achieved. The results shown are those that the application calculates through the smart government layer. This simple two-screen application also shows the economic benefit produced, the carbon footprint avoided by recycling, and other environmental information of general interest.

Mock-Up Simulation

To simulate the decisions taken by the architecture and by the users, a model has been developed by the BISITE Research Group. This model is designed to connect with multiagent architectures to evaluate the efficiency of IoT platforms in problems of energy optimization (demand response) or sustainability cities.

Fig. 1 Agent based Internet of Things platform.

In our case it has allowed us to simulate the results of the decisions of the algorithms of the architecture as to obtain the routes of waste collection by the shortest way using Dijkstra.

The model is designed in such a way that it can simulate from climatic conditions to electricity consumption by homes, neighborhoods, or regions defined by the user. In each of these neighborhoods is an electronic board, called cryptochip, which includes various sensors that can be referenced and integrated into different developments.

- The designed node has an accelerometer model LIS3DH with capacities to measure acceleration ranges from 0 to 16 g. This scale is dynamically adjusted according to the different needs of the moment.
- For temperature control, a TC1047A microchip sensor with ultra low power consumption of less than 35 μ A is available.
- For the positioning of the data it has a system of last generation of the manufacturer Ublox, the model MAX-M8Q able to obtain the positioning through the four global standards of positioning by triangulation: GPS, Galileo, GLONASS, and BeiDou, in this way the time is reduced to find a "fixed" of position and with it the initial consumption, the highest in this type of devices.
- The device is equipped with an HTFS 800-P power consumption sensor capable of withstanding voltages of up to 2 KV and amperage peaks of up to 800 A.

Fig. 2 Android application for the visualization of the achievements obtained by each user.

Fig. 3 BISITE Mock-up for the simulation of optimization problems, calculation of transport routes, sustainability problems in a smart city.

Fig. 4 Calculation of the route to be carried out by the garbage truck to collect the waste in a more optimal way, using the Dijkstra algorithm.

Fig. 5 Cryptochip board that manages the simulation of conditions and the sending of safe data in the model.

- It uses a LoRaWAN communication network based on LoRa modulation, due to its high noise tolerance and indoor penetration if necessary.
- ATSHA204A encryption chip with SHA1 technology.

This chip behaves like a generic gateway within the IoT paradigm. This implies that the strong points of the device are the security of the data it obtains from the environment, ensuring its reliability and in the same way transferring them safely to the upper layers of the developed architecture, being totally agnostic to them. Some of its functionalities are:

- *Data collection*, since it has the possibility of connecting multiple sensors in its pins allows to carry out a data collection depending on the type of project in which it is used.
- *Data encryption*, since it has a hardware encryption chip, it can apply an RSA signature to the data. This type of encryption algorithm is double key (public/private), therefore, the cryptochip can encrypt the information, send it, and in the destination application (or the blockchain itself) decrypt it to see the data.
- *Reading sensors*, thanks to its dedicated connectors, allows easy connection to several sensors simultaneously and have different methods of communication.
- *Reading and sending data in portable systems*, thanks to the possibility of being powered by a power bank and its low consumption, can be used in portable applications, in addition to carrying out the sending of data collected through the integrated communications modules thanks to the X-bee socket.
- *Integration in IoT systems*, thanks to the low consumption of the system, and the incorporation of wireless communication systems, allows the implementation of this board in IoT.

Fig. 6 Communication between agents for capturing data from the environment and the user's mobile application.

- *Traceability*, as the data collected and encrypted by the cryptochip that are sent to the blockchain have data from a GPS sensor, you can track precisely the path that has followed the cryptochip. For example, commercial transport containers, trucks, etc.
- *Internet of value*, has been built on open standards but its basis is blockchain technology. In this way we have a new tool (blockchain) to share and manage value of assets or goods without the need to depend on a trusted central entity that decentralizes the process.

Simulation Results

This section details the characteristics of the case study in which the architecture has been tested and the results obtained, to assess whether the proposed IoT platform presents an advance in citizen participation in the recycling process and in the process of optimization of waste collection routes. The system has been evaluated in the mock-up previously presented, simulating a real context. It has been simulated the characteristics of an urbanization with a population of 2200 inhabitants with 30 containers with the required infrastructure (10 blue containers for paper and cardboard, 10 yellow plastic waste containers, 10 green containers for glass), and 10 red containers of urban waste (these containers without the infrastructure).

The experiment has been divided into two phases; in the first phase the number of people who recycle and the amount of waste collected in each container has been counted, and in the second phase simulations were produced using the proposed architecture using gamma algorithms. In this second stage, the interaction of the 2200 inhabitants has been simulated, deploying agents with different behaviors based on their belief, desire, and intentions.

The process consists of each agent simulating a user who is logged by reading the QR code that identifies the container and identifies the user so as to enable the opening of the container deposit and weighing of waste. Once the waste has been introduced, the container has the quantity of waste, sends the data structure generated (quantity of waste, type of waste deposited, user that recycles, filling status of the container, occupancy rate of the nearest waste treatment plant) through the local retransmission antenna deployed using LPWAN.

The information arrives at the IoT platform and it is the agents of the different layers who are in charge of making decisions such as sending a truck to collect waste from a specific container if it is full or updating the bonus or penalty in the user's profile. Each agent allows you to visualize the achievements that your user has accumulated during the current month (each month the

Table 1 Quantity (kg) of waste collected from each container

	<i>Before system</i>	<i>After system</i>
Blue container	2214.15	2625.98
Yellow container	1731.24	2023.82
Green container	1595.07	1851.88
Total	5540.46	6501.68

profile is restarted, the achievements are not cumulative for the next month). If the user reaches the goals proposed by the municipality, the case study was proposed to increase the amount of waste by 18%. The users who obtained it obtained a reduction of 5€ on the monthly rate of rubbish (48€). At the end of the experiment, the amount of waste deposited was measured according to the simulated behavior to measure the efficiency of the system, as can be seen in [Table 1](#), in which an increase of 17.2% is observed.

Conclusion

This article presents a novel model of an agent based IoT platform that allows through gamification mechanisms to encourage citizen participation in recycling tasks. The gamification is presented as a key aspect in this type of IoT platform because the acquisition of data from the citizens of a neighborhood can propose challenges with which to increase the amount of waste to recycle.

As with any IoT platform, it is necessary to deploy an infrastructure in each container to provide information about the user's interaction with the gamification model, e.g., information about which user has recycled, amount of garbage introduced, in which container garbage has been deposited, or the occupation status of the container, among others. This information provides the necessary knowledge to the platform for the execution of the gamification model, as well as for the definition of optimal routes of waste collection according to the state of occupation of the containers and the nearest waste treatment plant, allowing an optimal and efficient management of urban waste.

The behavior of users has been recreated based on data from their real interaction in the recycling process in their city. This case study has allowed us to know the validity of the proposed platform without developing the technical deployment of the necessary sensorization. The results of evaluating the proposed platform have satisfactorily concluded the usefulness of the proposal. On the one hand, citizen participation has increased by 32.2%, the amount of waste has increased by 17.2% and, on the other hand, the number of journeys for waste collection has been reduced by 53.4%. It is clear that the use of gamification and the problem of encouraging recycling in cities allows citizens to reward their good behavior due to the savings produced by reducing the number of trips for waste collection and the increase in the garbage tax for those who do not carry out this task, apart from the other social benefits that recycling produces.

Future lines of work include the deployment of the hardware part of the platform for evaluation in a completely real scenario. This real scenario will certify the good results obtained. This platform will also allow the system to be used to carry out social measurements that will make it possible to know the behavior patterns of the users (average amount of waste it deposits, frequency with which it goes to the containers, timetable, days of the week, etc.).

Mechanical Properties of Composites From Discarded Carpets

Adeayo Sotayo, University of Liverpool, Liverpool, United Kingdom

Introduction

The issue of waste is a vital worldwide concern because waste is commonly discarded to landfill or incinerated, which subsequently releases greenhouse gases that contribute broadly to global climate change. In the UK alone, around 222 million tonnes of total waste was generated in 2014 (Department for Environment Food and Rural Affairs, 2018). Therefore, it is important to explore different ways in which discarded waste materials can be recycled or utilized as a resource. Furthermore, it is estimated that a tonne of waste materials being reused or recycled can save around 3 tonnes of CO₂ equivalent (Department for Environment Food and Rural Affairs, 2011).

More specifically, this article focuses on discarded carpets. Discarded carpets comprise different polymers and fillers, and can be classified as multilayered composite materials, which are expensive to reprocess and often challenging to mechanically separate at the end of their use. In the USA, about 1.5 million tonnes of carpets were discarded, and about 49 thousand tonnes were sent to landfill in 2017 (Carpet America Recovery Effort, 2018). Also, about 400,000 tonnes of discarded carpets are sent to landfill in the UK annually (Bird, 2018). Nonetheless, disposal of discarded carpets to landfill is gradually becoming difficult and impractical because of rising costs/taxation and decreased availability of landfill sites, nonbiodegradability of the synthetic fibers, and environmental impact considerations. The landfill tax associated with the disposal of discarded carpets to landfill in the UK was £24 in 2007 and has increased to £84 in 2016 reflecting a 250% increase over nine years (Gardner, 2016). The UK Government (2016) has a specific objective to reduce the amount of waste produced, whilst encouraging the increased use of alternative waste management options.

Aside from landfill, there are other processing alternatives for discarded carpets, which include energy recovery (via incineration), reuse, fiber reprocessing, plastics reprocessing, and equestrian surface applications. Energy recovery from discarded carpets via incineration involves shredding of the carpets, which are subsequently used as fuel to replace traditional sources, such as coal, for use in cement kilns or boilers. While this alternative has appeal and preferred to the landfill option, incineration of discarded carpets releases toxic greenhouse gas emissions.

Discarded carpet tiles may be reused (see Fig. 1) depending on their physical conditions, and the processing stages for reuse comprise cleaning, trimming, and possible recoloring. The reuse option is economical and leads to considerable savings in energy and raw material consumption as well as a reduction in greenhouse gas emissions. Fiber reprocessing involves the recovery of fibers from the discarded carpets by dissolving them in a chemical solvent, which enables the separation of the face fiber materials from the other carpet constituents.

Furthermore, fiber reprocessing can be used to develop textile products; for example, felt used as carpet underlay for both sound and heat insulation, as shown in Fig. 2. The use of discarded carpets for equestrian surface applications (see Fig. 3) pertains to shredding the fibers and mixing them with sand and/or waste tire rubber crumbs. Furthermore, the advantages of using discarded fibers for equestrian surface applications include better stability and dampening effect for the horses.

Plastics reprocessing of discarded carpets entails their use in engineered plastic solutions. This process involves shredding of discarded carpets at high processing temperatures, which can be extruded and injection molded into thermoplastics and/or composite materials. This is because the constituents of discarded carpets (i.e., polymers and fillers) form raw materials appropriate for the development of new composite materials and could potentially have a positive impact on the environment and yield economic benefits. The section "Processing Conditions and Mechanical Properties of Discarded Carpet Based Composites" focuses on some of the discarded carpet based composites developed and reported in the literature alongside their processing conditions and mechanical properties.

Types and Composition of Discarded Carpets

There are different manufacturing processes for making carpets, which include tufting, weaving, and needle-punching (The Carpet and Rug Institute, 2003). Tufted carpets are the most common (representing about 76% of total carpets) and have two major style categories (i.e., level-loop and cut-pile) (see Fig. 4). The large amount of tufted carpets could be attributed to their rapid production rate and cost-effectiveness. Woven and needle-punched carpets represent 12% and 9% of total carpets, respectively (Pakravan *et al.*, 2019). Other manufacturing methods and styles contribute to the remaining 3% of all carpets. Furthermore, based on their origin and source, discarded carpets can be classified into preconsumer and postconsumer discarded carpets. Generally, preconsumer discarded carpets include off-cuts during the production or fitting stage. On the other hand, postconsumer discarded carpets include those generated at the end of their useful lives and typically consist of chemicals, dirt, and flakes that build up during usage.

There are four main layers of a carpet, which include the face fibers, primary backing, secondary backing, and adhesive. Fig. 4 shows the arrangement of the layers in a typical carpet. The top layer is the face fiber, and the primary backing is the layer that the face fibers are attached to. The adhesive [usually made of styrene butadiene rubber (SBR)] is applied to the bottom of the primary backing to attach the layers together. Calcium carbonate (CaCO_3) or barium sulfate (BaSO_4) are typically added as fillers to the adhesive. The secondary backing is attached via the adhesive to the primary backing.

Fig. 4 Structure of carpets showing the four main layers: (a) level-loop and (b) cut-pile carpets.

Fig. 5 Typical percentage composition of carpet components. Reproduced from Ucar, M., Wang, Y., 2011. Utilization of recycled post consumer carpet waste fibers as reinforcement in lightweight cementitious composites. *International Journal of Clothing Science and Technology* 23 (4), 242–248. doi:10.1108/09556221111136502.

Carpet has an approximate areal density of 2.4 kg/m^2 and Fig. 5 shows the approximate percentage composition of carpet components, with the face fibers constituting about half of its total weight (Ucar and Wang, 2011). Carpets consist of different materials, which include nylon, polypropylene, polyester, jute, wool, polyethylene, SBR, and polyethylene terephthalate; their mechanical properties are given in Table 1. Although both synthetic fibers and natural fibers can be used to make the face fibers, polypropylene and nylon are the most common materials used as the face fibers and primary/secondary backing because of their durability.

Processing Conditions and Mechanical Properties of Discarded Carpet Based Composites

One of the primary objectives for the development of discarded carpet based composites is to attain suitable materials, which can be used for structural applications. The conversion of discarded carpets into useful products is a sustainable alternative approach to landfilling. Examples of practical applications for discarded carpet based composites are shown in Fig. 6.

The suitcase (namely *Terracase*) was developed from discarded wool carpets with the addition of a bioresin obtained from rapeseed oil (McLaughlin, 2013). Also shown in Fig. 6 are compression molded brackets used at the bottom of a clothing rack. As discarded carpets comprise different polymers, they can potentially be used for low/medium structural applications such as decking, furniture, park benches, and fencing (Sotayo et al., 2015). As such, discarded carpet based composites can deliver a practical and cost-effective option for a variety of engineering applications, and as a result of that, utilize large quantities of discarded carpets.

When the polymers in discarded carpets are heated, they are softened or melted; this can be shaped or formed, and solidifies when cooled. Several cycles of heating and cooling can be repeated on these materials without damage, thereby allowing multiple

Table 1 Mechanical properties of different materials found in carpets

<i>Polymer</i>	<i>Young's modulus (GPa)</i>	<i>Tensile strength (MPa)</i>
Polypropylene	1.2–1.7	50–70
Nylon	2.0–3.5	60–110
Low-density polyethylene	0.15–0.24	7–17
High-density polyethylene	0.55–1.0	20–37
Polyethylene terephthalate	2.2–3.5	50–80
Wool	3.9–5.2	40–200
Styrene butadiene rubber	0.002–0.010	12–21

reprocessing and recycling. Some of the studies from literature have demonstrated the feasibility of such composites and reported their mechanical properties. These studies also investigated the effect of utilizing other materials such as glass fibers, binding agents, and different polymeric matrices. The reported mechanical properties include flexural modulus, flexural strength, tensile modulus, and tensile strength. The modulus of elasticity of a material can be defined as the measure of the stiffness or its resistance to elastic deformation, and the strength is the maximum stress that the material can withstand before fracture. These aforementioned properties are essential for design and structural analysis.

Various manufacturing and processing conditions can be used to fabricate discarded carpet based composites, which include compression molding, intrusion molding, melt blending and hydraulic pressing, injection molding, and vacuum-assisted resin transfer molding. These different processing conditions occur at various pressures, temperatures, and processing times, which in turn could affect the mechanical properties of the discarded carpet based composites. In addition, the presence of contamination and degradation alongside pores, voids, and flaws during the manufacturing processes could significantly influence the mechanical properties of the final product.

Discarded carpets come from different sources, and many other factors can influence their mechanical properties. For example, the origin and type of discarded carpets. This is because discarded carpets are subjected to various in-service conditions and surroundings. Therefore, there are significant differences in the quantities of dirt/flake particles or chemical substances (from cleaning) embedded in discarded carpets, which subsequently leads to variations in the properties of the discarded carpet based composites. As discussed earlier, there are different types of carpets with different fractions and types of materials in it. Therefore, properties of the discarded carpet based composites can be influenced by the fraction and mechanical properties of the constituents and raw materials used in making the carpets.

The compatibility and miscibility of the polymers in discarded carpets are essential factors in influencing the properties of discarded carpet based composites. During the process of high-temperature extrusion or melt blending of the different polymers, the combination of two different polymers (for example nylon and polypropylene) can lead to a resultant composite with relatively weak mechanical properties, low quality, and poor structural integrity. Nevertheless, there are methods to improve these properties, which include the addition of polymeric binding agents (sometimes referred to as compatibilizers, compatibilizing agents, or coupling agents), matrices, additives, or fiber reinforcement.

The volume fraction or proportion and properties of the matrix and fiber reinforcement constitute to the mechanical properties of the resultant discarded carpet based composites. This is because these properties are dependent on the interfacial adhesion between the reinforcement and the matrix material (i.e., great interfacial adhesion will result in discarded carpet based composites with superior quality and good mechanical properties). Additionally, based on the rule of mixtures, the proportion or volume fraction of the fiber reinforcement or matrix material could affect the mechanical properties of the discarded carpet based composites. In general, the mechanical properties of discarded carpet based composites are significantly improved by adding fibers that have greater stiffness and strength properties in comparison to the polymers/materials present in the discarded carpets. For example, increasing the proportion of rigid reinforcement such as glass fibers will result in an improvement in the modulus of elasticity and strength properties, thus complying with the rule of mixture.

Composites With Discarded Carpet Fibers Without Matrix Addition

Table 2 gives the mechanical properties of discarded carpet based composites without matrix addition. Different types of discarded carpet based composites can be manufactured via different processes including compression molding, injection molding, and extrusion at a high temperature and pressure. They include preprocessing stages such as shredding of the discarded carpet fibers and granulation.

The production steps included shredding, granulation and extrusion of strips of discarded carpets, before being molded with no polymer addition or mechanical separation of carpet fibers (Sotayo *et al.*, 2018). The discarded carpets used included both those with natural fibers (such as wool fibers) and synthetic fibers (e.g., nylon). Experimental tests, which included tensile and flexural tests, were done on the discarded carpet based composites to determine their mechanical properties. The work showed that the flexural modulus ranged from 2.3 to 3.1 GPa, and the flexural strength from 25.9 to 31.8 MPa (see **Table 2**). The tensile modulus also ranged from 2.3–2.9 GPa, with tensile strength ranging 12.8–17.8 MPa. The study (Sotayo *et al.*, 2018) also stated that the mechanical properties of discarded carpet based composites demonstrate their potential as alternatives to common construction materials (e.g., timber and polyvinyl chloride) for fencing applications.

Compression molding was used to fabricate discarded carpet based composites, comprising nylon and polypropylene carpets (Pan *et al.*, 2016). The mechanical properties corresponding to each category of discarded carpets are given in **Table 2**. The tensile properties for the nylon and polypropylene carpet based composites are reasonably close. On the other hand, the flexural properties of the nylon carpet based composites are approximately 3–4 times greater than those from the polypropylene carpets (cf. nylon and polypropylene in **Table 1**). Also, compression molded composites from discarded nylon carpets have higher mechanical properties, which indicate their suitability for the construction and transportation sectors (Pan *et al.*, 2016).

Binding agents are typically added to enhance the miscibility and properties of the blended mixture, which also helps improve the adhesion between the different polymers. Young *et al.* (1998) produced some carpet based composites using discarded automotive carpets that comprised polyester and nylon fibers with the addition of a binding agent namely acrylic acid modified polypropylene polymer under the trademark PolyBond 1001. A combination of extrusion and injection molding was used to manufacture the discarded carpet based composites. The test results on the discarded carpet based composites showed tensile modulus and strength of 0.6 GPa and 11.8 MPa, respectively (see **Table 2**).

Table 2 Mechanical properties of discarded carpet based composites without matrix addition

Reference	Manufacturing process	Description	Tensile modulus (GPa)	Tensile strength (MPa)	Flexural modulus (GPa)	Flexural strength (MPa)
Sotayo <i>et al.</i> (2018)	Extrusion and hydraulic pressing	Polypropylene, nylon, polyethylene terephthalate, and wool carpets	2.3–2.9	12.8–17.8	2.3–3.1	25.9–31.8
Pan <i>et al.</i> (2016)	Compression molding	Nylon carpets	1.4	11.1	5.7	31.7
		Polypropylene carpets	1.8	9.9	1.4	11.8
Young <i>et al.</i> (1998)	Extrusion and injection molding	Discarded automotive carpets (nylon and polyester carpets) + 20 wt% binding agent (i.e., PolyBond 1001)	0.6	11.8	N/A	N/A
David <i>et al.</i> (1996)	Extrusion and injection molding	Nylon, polypropylene, and polyester carpets	1.7–2.7	13–31		
Murdock <i>et al.</i> (2011)	Extrusion	Polypropylene and nylon carpets + 5 wt% binding agent (i.e., Methylene Diphenyl Diisocyanate)	0.6	5		

On the other hand, discarded carpet based composites were produced with no binding agents or additives and achieved tensile modulus and tensile strength ranging from 1.7–2.7 GPa and 13–31 MPa, respectively (David *et al.*, 1996). The manufacturing process for the aforementioned composites entailed the passage of the melt blended fibers through a water bath and chopper, with the aim of producing pellets of high quality, before being injection molded.

Another method for making discarded carpet based composites entailed cutting and shredding the discarded carpets, which were subsequently mixed with Methylene Diphenyl Diisocyanate (binding agent) (5 wt%) before being extruded (Murdock *et al.*, 2011). The experimental tests on these discarded carpet based composites showed a tensile modulus and tensile strength of 0.6 GPa and 5 MPa, respectively, as shown in Table 2.

Composites With Discarded Carpet Fibers and Polyethylene Matrix

Polyethylene is a commonly used polymer used for plastic packaging (e.g., plastic bags/films), pipes, electrical insulation, and bottle containers. Polyethylene can be injection molded, blow molded, and extruded. Low-density polyethylene and high-density polyethylene are classes of polyethylene, and their mechanical properties are given in Table 1. Discarded carpet based composites have been developed using polypropylene fibers in a polyethylene matrix.

In the work by Gawayed *et al.* (1995), the composites were compression molded with the carpet fibers constituting approximately 25% fiber volume fraction. Their mechanical properties are given in Table 3. The work showed that adding the carpet fibers to low-density polyethylene led to a substantial increase in their mechanical properties in comparison to pure polyethylene. More specifically, the tensile and flexural moduli increased from 0.15 GPa and 0.086 GPa to 0.57 GPa (280% increase) and 0.137 GPa (60% increase), respectively. Similarly, the tensile and flexural strengths increased from 9 MPa and 13.8 MPa, to 38.5 MPa (330% increase) and 15.5 MPa (12% increase), respectively.

Also, a different process, namely intrusion molding (combination of injection molding and extrusion), was used to make discarded carpet based composites (Xanthos *et al.*, 2002). The discarded carpet based composites comprised 20 wt% of low-density polyethylene matrix and 80 wt% of carpet residue feedstock (containing polypropylene fibers, SBR, and calcium carbonate). The flexural modulus and strength of the discarded carpet based composites were 1.48 GPa and 15 MPa, respectively (see Table 3).

Composites With Discarded Carpet Fibers and Epoxy Matrix

Epoxy matrix is an important and commonly used thermoset material and has been widely used in reinforced composites, structural adhesives, and metal coatings because of their great mechanical properties and excellent chemical resistance. It is typically made by combining two components (i.e., hardener and resin) together. The Young's modulus of epoxy ranges from 2.1 to 5.5 GPa and the tensile strength ranges from 40 to 85 MPa (Ashby and Jones, 2006).

Vacuum-assisted resin transfer molding was used to manufacture composites from discarded carpets (Jain *et al.*, 2012). The manufacturing process encompassed the infusion of epoxy resin into the carpet layers, which were cured under pressure to form composite laminates. The flexural modulus and strength of the discarded carpet based composites ranged from 1.4 to 2.3 GPa and 24 to 35 MPa, respectively (see Table 4). Furthermore, this manufacturing technique showed that these discarded carpet based composites had excellent noise absorption properties suitable for use in infrastructure, transportation, and sound barrier walls (Mishra and Vaidyanathan, 2019).

Composites With Discarded Carpet Fibers and Phenol-Formaldehyde Matrix

Phenol-formaldehyde matrix is also a commonly used thermosetting resin and is produced via the reaction of phenol and formaldehyde. Phenol-formaldehyde matrix has good chemical and thermal resistance and has a wide range of applications, which include coatings, thermal insulation composites, molded products, and structural adhesives. The Young's modulus of phenol-formaldehyde is about 8 GPa, and the tensile strength ranges from 35 to 55 MPa (Ashby and Jones, 2006).

Table 5 Mechanical properties of discarded carpet based composites with glass fibers

Reference	Manufacturing process	Description	Tensile modulus (GPa)	Tensile strength (MPa)
Zhang <i>et al.</i> (1999)	Injection molding	Pure discarded carpets without glass fibers	1.43–1.51	18–30
		Carpet composite with 40 wt% glass fibers	5.7–6.8	84–109
	Compression molding	Pure discarded carpets without glass fibers	1.72	25.5
		Carpet composite with 20 wt% glass fibers	2.12	40.7
		Carpet composite with 30 wt% glass fibers	2.76	55.2
		Carpet composite with 40 wt% glass fibers	5.90	84.1
Muzzy (2006)	Injection and compression molding	Description	Flexural modulus (GPa)	Flexural strength (MPa)
		Pure discarded carpets without glass fibers	0.86–2.7	31–70
		Carpet composite with 30 wt% glass fibers	2.0–5.7	54–147

Carpet based composites have been developed from discarded carpets enclosed in a relatively high modulus phenol-formaldehyde matrix (20 wt% volume fraction) (Kotliar, 1999). The discarded carpet based composites entailed a honeycomb sandwich structure, with the phenol-formaldehyde used to coat the fibers in the outer layers. Experimental results showed that the flexural modulus and flexural strength of the discarded carpet based composites with phenol-formaldehyde matrix were 6.9 GPa and 69 MPa. The relatively higher modulus of the discarded carpet based composites can be attributed to the high modulus of phenol-formaldehyde as well as its honeycomb sandwich structure design, which gives enhanced bending stiffness from a structural design perspective (Kotliar, 1999).

Composites With Discarded Carpet Fibers and Glass Fibers

Manufacturers use glass fibers as reinforcement materials in conventional composites (e.g., glass fiber reinforced plastic) because of their high mechanical properties. More specifically, glass fibers have tensile moduli and strengths that range from 69 to 83 GPa and 3500 to 4600 MPa, respectively (Strong, 2008).

These glass fibers can be mixed and compounded with discarded carpet fibers to obtain resultant composites with improved mechanical properties. Injection molding and compression molding processes were used to manufacture discarded carpet based composites with the inclusion of glass fibers (Zhang *et al.*, 1999; Muzzy, 2006). Table 5 gives the details and mechanical properties of these composites.

The data shows that the tensile modulus and tensile strength of the injection molded discarded carpet based composites (without glass fibers) were 1.43–1.51 GPa and 18–30 MPa, respectively (Zhang *et al.*, 1999). Similarly, the compression molded discarded carpet based composites (without glass) had a tensile modulus of 1.72 GPa and a tensile strength of 25.5 MPa. Therefore, the aforementioned mechanical properties of the discarded carpet based composites (without glass) are reasonably close. Furthermore, as shown in Table 5, an increase in the proportion of glass fibers in the discarded carpet based composites led to improvements in their mechanical properties. For example, the tensile modulus of compression molded discarded carpet based composites (with 40 wt% glass fibers) was 5.90 GPa, reflecting a 243% increase. Also, the tensile strength increased from 25.5 MPa to 84.1 MPa (230% increase).

A similar trend is shown in the flexural properties of the injection and compression molded discarded carpet based composites with 30 wt% glass fibers (Muzzy, 2006) (see Table 5). It is, therefore, demonstrated that the inclusion of glass fibers substantially increases the mechanical properties of discarded carpet based composites (Zhang *et al.*, 1999; Muzzy, 2006). This increase can be attributed to relatively greater stiffness and strength properties of glass fibers in comparison to other commonly used polymers.

Concluding Remarks

The challenges associated with waste materials are critical to the global economy and affect the issue of climate change. About 1.5 million tonnes of discarded carpets were generated in the USA in 2017, and about 400,000 tonnes of discarded carpets are sent to landfill annually in the UK. Discarded waste to landfill is a significant concern because of environmental impact considerations, decreased availability of landfill sites, nonbiodegradability of the synthetic fibers, and increasing landfill fees. Apart from the landfill option, this article also discussed some of the other processing options for discarded carpets such as energy recovery (via incineration), reuse, fiber reprocessing, plastics reprocessing, and equestrian surface applications.

Sustainability is a major objective of the global environmental agenda; therefore, it is important to explore various methods of utilizing discarded carpets as a resource or raw materials rather than being viewed as waste. The development and extensive characterization of discarded carpet based composites provide new possibilities for the efficient use of waste materials. As discarded carpets comprise different polymers and fillers, they can potentially be used to make composite materials for construction and other structural applications. Hence, this article has provided fundamental mechanical properties of discarded carpet based composites alongside their manufacturing processes (e.g., injection and compression molding). Also, recent developments

and applications of discarded carpet based composites were given. The effect of different materials (e.g., glass fibers, polyethylene, and epoxy) and additives/fillers or binding agents on the mechanical properties of discarded carpet based composites was discussed. For example, binding agents can be added to improve the compatibility and miscibility of different carpet constituents. Also, the inclusion of glass fibers in discarded carpet based composites gives a substantial improvement in their mechanical properties. Therefore, recycling of discarded carpets into useful composite materials and products offers not only a positive environmental impact but also economic benefits.

Introduction

A life without depending on plastic cannot be imagined given the present scenario. Plastics have become hugely important in terms of human needs over the past 100 years. It is predicted that by 2050, the worldwide generation of plastics will surpass 500 million metric tonnes. Sadly, it is also predicted that there will be more plastics in the ocean than fishes due to improper mismanagement and inefficient and poor recycling techniques (Sardon and Dove, 2018). Most of the traditional plastics generated are highly persistent and less degradable due to the presence of highly packed complex carbon chains that are difficult for microorganisms to degrade, resulting in a time-consuming breakdown process (Koushal *et al.*, 2014). As a result of improper management of plastics, the next generation will be faced with toxic chemicals that will seriously affect the environment and all living organisms, causing further damage in the generations to come (Gregory, 2009). Among various countries associated with plastic leakage to the marine ecosystem China has the highest, at 1314.1–3527.9 thousand tonnes annually, and Denmark the lowest, with 0.3–0.7 thousand tonnes (Table 1). China, India, Brazil, and the USA are in the top 20 countries with the highest plastic marine debris entering the ocean. However, while China and India top the list for population, they are near the lowest gross domestic product (GDP) per capita between the eight countries. These countries represent a range of mismanaged plastic, population, and GDP. The cities themselves cover a geographical spread, varying levels of development and legal systems, appearance on the Green Cities Index (Axelsson and van Seville, 2017).

About 90% of the plastics used in automobiles, electrical gadgets, medical applications, and in other sectors are virgin in nature. The demand for plastic in various areas is exhibited in Fig. 1. About 14% of plastic is recycled and used for low-value applications. The recent decline in oil prices resulted in a reduction of virgin plastics costs, which made it harder for recyclers to compete. As a result, most of the plastic products are discarded after a single use (Carey, 2017).

On the other hand, the main hurdle is identifying suitable technologies to produce high-quality value recycled plastics that exhibit the same properties as virgin plastics. The presence of additives, fillers, and other composites in plastics and the cross-contamination of other products will make the recovery of plastics very difficult. It has been predicted by 2050, about 12,000 metric tonnes of plastic waste will accumulate in the natural environment or landfills if the prevailing improper waste management methods and uncontrolled plastic production are continued (Geyer *et al.*, 2017). These challenges can be surpassed by identifying proper assimilation methods of plastics, recovery processes, and improved separation technology (Shen and Worrell, 2014). This article focuses on discussing various recycling methods of bulk plastics. These include an overview of waste management, challenges of plastics recycling, systems for plastic recycling, properties of recycled plastics, application in various fields, environmental aspects of recycled plastics, and future directions (Fig. 2).

Table 1 Plastic leaked to the marine environment

Country	Plastic seepage from land to ocean (Thousands T/year) based on Jambeck <i>et al.</i> (2015) (2010 values)	Population in (millions) (The World Factbook – Central Intelligence Agency, n.d.)	GDP/capita (US\$) (The World Factbook – Central Intelligence Agency, n.d.)
Denmark	0.3–0.7	5.6	46,600
Singapore	1.0–2.6	5.8	87,100
Canada	1.2–3.2	35.4	46,200
Australia	2.1–5.6	23	48,800
USA	41–110.2	324	57,300
Brazil	70.2–188.6	205.8	14,800
India	89.4–239.2	1266.9	6700
China	1314.1–3527.4	1373.5	14,600

Abbreviation: GDP, gross domestic product.

Plastic Waste Management

Plastic waste mismanagement is a critical issue affecting different parts of the world due to the uncontrolled generation rate and improper waste management and disposal technologies. India is a significant contributor to plastic production comprising about 16% per annum and faces lots of plastic solid waste (PSW) issues ([British Plastics Federation, 2012](#)). Recently, the government of India has formulated plastic waste management (PWM) rules in 2016, which should be followed by Indian citizens ([Ministry of Environment, Forest and Climate Change, 2016](#)) ([Figs. 3, 4, 5 and 6](#)).

Some of the key aspects of these PWM rules are listed below:

- To enhance the recycling of plastics, the thickness of plastics was raised from 40 to 50 μm . By raising thickness, the cost of plastic bags increased 20%.
- Implementing PWM rules in rural areas.
- The effective arrangement of a collection of waste materials from importers, production units, and brand owners.
- Segregation of waste plastics by the institutional sectors and delivery to authorized persons for further treatment or disposal.
- Waste to energy applications should be encouraged.
- Land allocation for proper plastics disposal should be facilitated by the state government.

According to the European Commission, effective recycling of plastics comprises the following steps ([European Parliament, n.d.](#); [Interreg Europe, n.d.](#)):

- Characterization studies to analyze the strength and weakness of recycled waste plastics.
- Complete recycling of packaging plastics by 2030.
- Reduction or avoidance for single-use plastic utilization.
- Identifying mold designs for preparing suitable products in recycled plastics.
- Advancement in polymer quality utilizing the inclusion of compatibilizers or additives and evaluating the cost-effective approaches.
- The overall resource efficiency of recycling process evaluated by life cycle costing and life cycle analysis (LCA) studies and assuring the best possible way of using recycled plastics and giving awareness to the public about the importance of recycling ([Ragaert, 2016](#)).

Methods for Bulk Plastics Recycling

The most common methods used for PWM are recycling mechanisms. Recycling of bulk plastics is carried out by the closed loop and open loop recycling. In closed loop recycling, the recycled waste plastics are used to generate similar products to that of virgin plastics. The Polyethylene terephthalate (PET) polymer in packaging is a typical example of utilizing closed loop recycling. In open

loop recycling, the recycled bulk plastics are used to generate different products compared with their original form. Examples include PET bottles and components in printers (Gort and Gerrits, 2015) (Table 2).

There are four categories of recycling mechanisms. In the primary category, mechanical reprocessing of waste plastics to a product with similar properties takes place. Physical treatment of bulk plastics is carried using pulverizing, incineration, and grinding mechanisms to minimize the size of waste plastics (Al-Salem *et al.*, 2009). Physical treatments are categorized as either thermal, UV radiation, or photooxidation processes (Orr *et al.*, n.d.). Complete disposal of bulk plastics is one of the limitations in physical treatment, which ultimately results in the generation of hazardous environmental by-products (Gilpin *et al.*, 2005).

Fig. 6 Various plastic solid waste alternatives concerning polymer product lifecycle. Reproduced from Ragaert, K., Delva, L., Van Geem, K., 2017. Mechanical and chemical recycling of solid plastic waste. *Waste Management* 69, 24–58. doi:10.1016/j.wasman.2017.07.044.

Table 2 Overview of the advantages and challenges of various techniques for recycling solid plastic waste

	<i>Techniques</i>	<i>Advantages</i>	<i>Challenges</i>
Mechanical recycling and sorting	Flotation (sink-float)	Well-known technology; Cost-effective	Efficiency determined by density differences plastics Mainly limited to binary mixtures
	Melt filtration	Useful to remove nonmelting contaminants; particle size	Potential pressure fluctuations in production
	FT-NIR	Postdrying not required	Plastic should be dry; black undetectable
	Electrostatic separation	Small particle sizes allowed; Efficient for various plastics	Pretreatment
	Froth Flotation	Efficiency	Precursor step required
	Magnetic density separation	Multiple polymer fractions in a single step; Improved density-based technique	Density overlaps remain
	X-ray detection	Useful for PVC; accuracy	Cost-effectiveness
Reprocessing		High-value recycling; straightforward	Challenging for complex mixtures; thermal–mechanical degradation; miscibility of polymer blends
Chemical recycling	Chemolysis	Operational for PET; generates pure value-added products	Mainly limited to condensation polymers; requires high volumes to be cost-effective
	Pyrolysis	Suitable for highly heterogeneous mixtures of plastics	Suitable for highly heterogeneous mixtures of plastics; complexity of reactions; stable waste supply; low tolerance for PVC
	Fluid catalytic cracking	Less stringent reaction conditions lead to favorable economics; narrow product outcome	The absence of suitable reactor technology; deactivation of the catalyst; presence of inorganics
	Hydrocracking and combined	Different elements already commercialized; suitable for mixtures of plastics; quality of produced naphtha	High investment and operational costs; high cost of hydrogen; further research required
	Catalytic pressure less depolymerization	Also suitable for oxygen and halogenated compounds	Lack of technical information; chemistry still unknown
	Gasification	Syngas is a valuable intermediate	Specific drawbacks of air; presence of toxic gases

Abbreviations: PET, polyethylene terephthalate; FT-NIR, fourier transform near infrared; PVC, poly-vinyl chloride.

Note: Reproduced from Ragaert, K., Delva, L., Van Geem, K., 2017. Mechanical and chemical recycling of solid plastic waste. *Waste Management* 69, 24–58. doi:10.1016/j.wasman.2017.07.044.

The secondary level involves mechanical reprocessing of waste polymers to products that require decreased properties (Delva *et al.*, 2018b). In the tertiary level, the chemical constituent of polymers is recovered employing depolymerization which comes under chemical or feedstock recycling (Achilias *et al.*, 2012). Biological recycling is another example of tertiary recycling, which involves the degradation of plastic polymers that can be easily decomposed by microorganisms (Alaerts *et al.*, 2018).

Incineration involves the energy recovery from waste, which falls under the quaternary category of recycling. The incineration method is used for recycling packaging and medical applications (Ignatyev *et al.*, 2014). However, the incineration of mixed plastics generates furans and dioxins, which are toxic to the environment and living beings. Even though incineration limits the needs for plastics sorting, it does not conserve much energy compared with other recycling mechanisms (Rahimi and Garc  a, 2017). Hence this method in PSW is not highly encouraged (Lopes *et al.*, 2015). Landfilling of plastic waste is often inefficient and toxic to the environment because the plastic wastes are decidedly less biodegradable; therefore, more accumulated waste will contaminate groundwater and soil properties (Hidayah and Syafrudin, 2018).

Some of the emerging technologies in PSW are polymer integrated bitumen roads, plasma pyrolysis, use of plastic waste as an alternative fuel, and cement kiln coprocessing. Waste plastic polymers such as Polypropylene (PP), Polystyrene (PS), and Polyethylene (PE) are integrated with bitumen, and the mixture is used for pavement applications.

The blending of plastic wastes with bitumen enhances durability and has been found to be successful for constructing flexible pavements (Manju *et al.*, 2017). The plasma pyrolysis method was used to convert waste plastics to useful energy through catalytic and thermal methods of degradation (Sharuddin *et al.*, 2018). Thermal pyrolysis of waste bulk plastics into liquid has shown several advantages compared with other recycling mechanisms. The conversion of waste plastics to liquid fuel facilitated by a catalyst under low temperature was found to be feasible. The liquid fuel produced was found to be applicable as a blending agent with kerosene or gasoline (Garieballa, 2014). The useful liquid fuel generated was identified to be a potential energy source in various applications such as boilers, furnaces, and diesel engines (Bridgwater, 2012). The use of waste plastics in cement kilns is found to be a potential PSW mechanism. The high-temperature condition of cement kilns helps in using even some toxic plastic waste without creating many environmental impacts (Baidya *et al.*, 2016). There is no requirement for cleaning or separation of this disposal method. Hence low-value end plastics wastes act as a vital source of energy for the cement industry (Asamany *et al.*, 2017).

Systems for Plastic Recycling

Mechanical Recycling

Mechanical recycling mechanism consists of converting waste plastics into a suitable product that exhibits similar properties as compared with virgin polymers (Vanapalli *et al.*, 2019; Delva *et al.*, 2018a; Chandrasekaran and Sharma, 2019; Hahladakis *et al.*, 2018). Thermoplastics can be used for mechanical recycling because they can be easily remelted and processed again to suitable products (Ruj *et al.*, 2015). Mechanical recycling involves the following steps (Figs. 7 and 8):

- Segregation sorting is carried out based on properties such as color, density, shape, and size or chemical component of waste plastics.
- Baling: Plastic baling is used to convert any waste plastics into useful commodities and is used when the bulk plastics have not undergone processing.
- Cleaning: Organic contaminants from waste plastics are removed by washing.
- Sizing: Reduction in size of waste plastics into fragments is carried out by grinding mechanism.
- Pelletizing: This is the final step, which involves the molding or reprocessing of waste plastics into suitable pellets, which would be more accessible for use in converters.

Separation techniques and process description

The segregation of waste plastics is carried out by manual sorting and automatic sorting. Manual sorting is highly productive but labor intensive. Automated sorting of waste plastics is carried out by Fourier transform near infrared technique. However, the drawback is that this method is not well suited to distinguishing dark or black plastic products.

Since it is an optical surface based technique there are chances of the sensor showing false reading due to the presence of dirt in the waste plastics; as a result, light cannot be adequately reflected (Ruj *et al.*, 2015). The electrostatic separation technique is found useful in separating binary mixed waste plastics. Examples include PE/PP and PET/Poly-vinyl chloride (PVC) mix polymers (Reinsch *et al.*, 2014). The sorting process begins by stocking the waste plastics into a belt system from where the mixture is transferred to a shredder where size reduction of the polymer occurs (Jung *et al.*, 2018). From there the wastes undergo washing using a rotating drum in which glass, rocks, and metals are removed by force of gravity supported by water flow for washing.

Friction washers remove the organic contaminants adhering to waste plastics. Now, the larger particles undergo shredding to result in particles from 1 to 12 mm. Density-based separation of waste plastics is carried out by float-sink separation method (Qing *et al.*, 2015). X-ray technique is used for sorting PVC polymers by detecting the presence of chlorine content

Fig. 7 Plastics, metals and drink carton sorting method for industries. Reproduced from Ragaert, K., Delva, L., Van Geem, K., 2017. Mechanical and chemical recycling of solid plastic waste. *Waste Management* 69, 24–58. doi:10.1016/j.wasman.2017.07.044.

Fig. 8 Flowchart of various processes involved in mechanical recycling of polycarbonate waste polymer. Reproduced from Ragaert, K., Delva, L., Van Geem, K., 2017. Mechanical and chemical recycling of solid plastic waste. *Waste Management* 69, 24–58. doi:10.1016/j.wasman.2017.07.044.

(Arvanitoyannis and Bosnea, 2001). Froth flotation mechanism is used to sort waste polymers with uniform densities (Censori *et al.*, 2016).

Removal of ferrous components from the waste is facilitated by providing a strong magnetic field in the sink fraction and transferred to the mechanical drier. Magnetic separation using density technique is efficiently used for the segregation of waste polymers such as PE and PP from mixed polyolefins and for rubbers and PVC from constructional wastes (Serranti *et al.*, 2015; Luciani *et al.*, 2015). The float-sink fraction experiences drying and then encounters a wind sifter where mass-based separation occurs. The separation of soft plastic particles such as low-density polyethylene (LDPE) and PP occurs in upward airflow while the hard particles such as high-density polyethylene (HDPE) tumble against airflow. Since the bulk density of soft particles is too low, it is used readily by converters and finally undergoes granulation by the extrusion process (Stenvall and Boldizar, 2016). This process helps in removing nonmelting contaminants during melting and enhances the overall quality and stability of the polymer (Luijsterburg *et al.*, 2016). The hard particles are further used as a secondary resource.

Mechanical properties of plastics

Mechanical properties of bulk plastics help in the identification of elastic and strength properties of the plastic polymers and can be used for specified applications (Scott, 2000). Tensile strength specifies the hardness, firmness, and strength of plastic polymers. The tensile strength test is one of the essential factors in evaluating the mechanical properties of bulk plastics. This test helps to analyze the strength and capacity of various plastic polymers and evaluating the efficiency to combat loading in various applications (Ferreira *et al.*, 2005). Elongation is another property of plastics. The efficiency of polymer breakage at a specific elongation is studied using the polymer breakdown test. Polymer elongation is influenced by various external agents such as exposure to UV radiation, sunlight, and temperature conditions (Pedroso and Rosa, 2005).

Another essential mechanical property of plastic polymers is that of *Young's modulus*. This property is used to determine the firmness of polymers. Elastic modulus varies with fluctuations in temperature. The elastic behavior of the polymer is examined by means of the elastic modulus test calculation. The stress–strain correlation of various polymers is determined by Young's modulus (Pedroso and Rosa, 2005).

Challenges for mechanical recycling

During the mechanical recycling process, two types of polymer degradation take place, namely thermal–mechanical deterioration and life degradation (La Mantia, 2004). During melt processing, thermal–mechanical deterioration of plastic polymers through mechanical shearing and heating occurs (Beyler and Hirschler, 2002).

During the degradation process, splitting of the carbon covalent bond takes on a polymer backbone and generates free radicals. These free radicals, after going through chemical reactions, result in branching or chain scission. Chain scission diminishes the molecular weight and overall properties of plastic polymers. On other hand, the chain branching leads to cross-linking and enhancement of the molecular weight of the polymer. A typical example of chain scission occurs in PP; similarly, PE is a typical example of chain branching (Pinheiro *et al.*, 2004). To overcome the drawbacks of thermal–mechanical degradation, certain additives such as heat stabilizers, compatibilizers, pigments, and cross-linkers are added during the recycling of bulk plastics and found useful in the enhancement of plastic recycling rate (Tostar, n.d.). The mechanical properties and melt strength during recycling of PET polymer are enhanced by postcondensation method (Dimonie *et al.*, 2012).

The second type of thermal–mechanical degradation of polymers is lifetime degradation. This degradation occurs during exposure of bulk plastics to heat, light, oxidation, hydrolysis, and mechanical shearing (Ragaert *et al.*, 2017). The photooxidation process results in the generation of oxygenated groups on the surface of polymers and affects the properties of plastics. The presence of an oxygenated group is determined by mass spectroscopy techniques (Xiang *et al.*, 2002). Polyethylene and PET plastics are commonly recovered using mechanical recycling due to limitations mentioned earlier. Since each plastic differs in physical, chemical, thermal, and mechanical properties, the mechanical recycling of waste plastics seems to be challenging (García and Robertson, 2017). Since mixed polymers vary in treating temperature and melting point, recycling of bulk plastics is challenging. This results in the deterioration of polymers having a low melting point and diminishes the overall properties of recycled plastics (Ragaert *et al.*, 2017).

Chemical Recycling

The plastic waste can be utilized as feed in the production of hydrocarbon-based fuel and other valuable chemicals. The current scenario is not only limited to recovering energy or with mechanical recycling, but also focusing on recovering valuable petrochemical feedstocks and monomers. With plastic feedstocks such as nylon, polyurethane (PUR), and PET the chemical recycling options can be successfully utilized, and there is a tremendous increase in their utilization as feedstock for the recovering of high hydrocarbon content. Plastic waste entails high carbon yield and limited oxygen concentration level. In the following sections, different technologies associated with recycling and treatments of bulk plastics are discussed. The leading technologies associated with these feed streams are hydrocracking, pyrolysis, gasification, and fluid catalyzed cracking.

Chemolysis

The chemically recycled plastics are more appropriate for food applications and have expanded interest in diverse chemolysis capabilities. Chemical recycling techniques open new dimensions for new value-added products for broad commercial and industrial applications. The chemically recycled polymers are not economically feasible compared with virgin material as a result of the scale of operation, capital investment, and raw material cost (George and Kurian, 2014) (Fig. 9).

Polyethylene terephthalate: Chemically recycling

PET can be depolymerized into the following monomers: Dimethyl terephthalate, terephthalic acid (TPA), ethylene glycol (EG), and bis terephthalate. PET can also be partially depolymerized to oligomers and other substances. Various depolymerization techniques such as glycolysis, methanolysis, aminolysis, ammonolysis, hydrogenation, and hydrolysis rely upon chemical agents used for PET chain scission.

PET methanolysis depends on the treatment of PET with methanol at high-pressure levels between 20 and 40 atm and high-temperature ranges of 280°C. The degraded products of PET after aminolysis and glycolysis find potential applications as chain extenders, plasticizers, corrosion inhibitors, precursors, and cross-linking agents in the production of by-products such as textile dyes, PURs, resins, vinyl esters, epoxy resins, and antibacterial drugs.

The reaction of PET with water under basic, acidic, and neutral environmental conditions at high pressure and temperature, breaks the polymer chains down into EG and TPA; this reaction process is known as hydrolysis. The main drawbacks are the low purity of TPA and the fact that this is a comparatively slow option since it is a weak nucleophile. Glycolysis is the traditional and most straightforward technique for PET depolymerization. Glycolysis is a commercial PET recycling technique still followed by various industries to handle large quantities of PET (Ragaert et al., 2017).

The transesterification of PET with excess glycol at a temperature level of 250°C guides the development of bis(hydroxyl ethylene) terephthalate. This technique is preferred when PET feed is of high quality and not recommended for removal of low levels of copolymers. Different glycols, such as EG, diethylene glycol, propylene glycol, polyethylene glycol, 1,4-butanediol, and hexylene glycol, are used for the glycolysis of PET. Glycolysis of PET undergoes three substages: Monomers, dimers, and oligomers (George and Kurian, 2014).

Super and subcritical fluids such as alcohol and water are exceptional media for carrying out decomposition of plastics. The super and subcritical fluids could decompose the polymers more selectively and rapidly. Condensation polymers can easily be depolymerized into monomers in the absence of alcohol or water, which can act as both solvent and reactant. The thermosetting resin in flame-retardant polymers can be recycled to materials with the aid of hydrolysis using subcritical aqueous media. The by-products, fumaric acid and glycols, dissolved in the aqueous solution can be recovered and separated.

Fig. 9 Various methods for chemolysis of polyethylene terephthalate polymer and evolved value-added materials. Reproduced from Ragaert, K., Delva, L., Van Geem, K., 2017. Mechanical and chemical recycling of solid plastic waste. *Waste Management* 69, 24–58. doi:10.1016/j.wasman.2017.07.044.

Pyrolysis

Pyrolysis emerges as an exciting option for recycling of bulk plastic feeds that are difficult to recycle such as mixed PP/PE/PS, multilayer packaging, demolishing, and PUR construction wastes. These types of multilayered films seem challenging in recycling compared with other waste streams. The multilayered plastic package containers opt for PE as it is both cheap and also provides structural and bulk integrity. However, if more thickness is required, manufacturers prefer PET as it is more suitable for beverage containers.

In blocking oxygen contact with beverages, ethylene vinyl alcohol is the preferred option compared with nylon, PET, or PE. The metalized film has also been incorporated to provide an increase in thickness. The recycling of these package containers creates new challenges in mechanical recycling as it is not considered as effective; therefore, pyrolysis arises as a better option. **Fig. 10** demonstrates the typical plant design and workflow of the pyrolysis process. The pyrolysis process can handle heterogeneous mixtures, and contaminated plastic waste streams provide more flexibility in handling waste streams. However, economic viability is the main drawback of this process (Vermeulen *et al.*, 2011; Al-Salem *et al.*, 2010).

The pyrolysis process carried out at the high-temperature level of 500°C in the absence of oxygen allows for the breakdown of the macrostructure of polymers into smaller and simpler molecules. The by-products of the pyrolysis process can be decomposed into three main fractions: Solid, gas, and liquid (Al-Salem *et al.*, 2010). The most impenetrable part in pyrolysis is the occurrence of complexity when mixed waste streams are processed together. According to the nature and the composition of plastic streams, different plastics give rise to different by-products in their decomposition process. The process is sensitive; even the presence of certain impurities can affect the by-products derived or even make it lose its standard properties (Garforth *et al.*, 2004). To carry out the pyrolysis process in a cost-effective manner, it can only be achieved by through large volumes. PP, PE, PVC, and PS are more suitable and appropriate waste sources for conversion to either petrochemical fuels or monomers (Ragaert *et al.*, 2017). However, the complexity of sorting out these plastic sources from mixed waste, a distillation of obtained by-products and complex separation technologies, creates a barrier in the global acceptance of pyrolysis technology. The presence of acid, chlorine, and other toxic substances also affects the by-products quality; the pretreatment for the removal increases the expenses and operational cost. Stirred tank reactor, screw reactor, and bubbling fluidized bed reactors are most commonly utilized reactors for the pyrolysis process (Butler *et al.*, 2011). The fluidized bed reactor is the most favorable option due to its high conversion rates. However, in recent years, a new disruptive reactor design, known as the vortex reactor, has been developed.

The vortex reactor upgrades the traditional reactor's designs by improving the convective heating between phases, providing flexibility with the option of different fluidization agents, and high centrifugal acceleration (Ragaert *et al.*, 2017). A vast number of parameters influences the pyrolysis process such as temperature, composition, stable supply of water, fluidizing gas, and macrostructure of polymers (Marongiu *et al.*, 2007).

Fig. 10 Classic pyrolysis process flow diagram along with recent vortex reactor technology for treating bulk plastics. Reproduced from Ragaert, K., Delva, L., Van Geem, K., 2017. Mechanical and chemical recycling of solid plastic waste. *Waste Management* 69, 24–58. doi:10.1016/j.wasman.2017.07.044.

Fluid catalytic cracking

The use of the catalyst in thermal decomposition, allowing for the direct recovery of fuel and other by-products, depends on the process conditions. Additionally, the catalyst minimizes the energy requirements, stringent reaction conditions, and overall operational expenses in thermal decomposition plants (Thegarid *et al.*, 2014; Passamonti and Sedran, 2012). On a comparison analysis of catalytic cracking and convention thermal decomposition, it was observed that the shifting of product spectrum towards smaller carbon numbers additionally resulted in the formation of naphthenic and aromatic compounds, which were also observed in catalytic cracking.

Catalytic cracking is of two major types: Vapor phase and liquid phase. In the vapor process, the vapors derived during cracking come in contact with vapors. Similarly, in the liquid phase process, the molten polymer is in direct contact with the catalyst. The catalyst aids to carry out the pyrolysis process at a lower temperature level of 300–350°C and yields towards aromatics and iso-alkanes, suitable for gasoline products (Buekens and Huang, 1998). However, the catalytic cracking has severe downsides such as the presence of inorganic compounds can block the pores. This ultimately leads to the deactivation of catalysts, carbonaceous deposits, the requirement of pretreatment, and limitations in reactor designs.

Hydrocracking

The presence of hydrogen at temperature levels between 375°C and 400°C and at a pressure of 70 atm improves the by-product quality, that is, low aromatic content and higher C/H ratio. Catalysts such as NiMo/S or Ni/S have been employed. Hydrocracking yields better naphtha feed and mixtures of bulk plastic feed can be used. However, the hydrogen-based process involves high operational and investment costs. Integrating hydroconversion and hydropyrolysis is a catalytically based thermochemical conversion process of converting the organic materials into value-based hydrocarbon by-products. This process can handle municipal waste, cellulosic fractions, biomass residues, and plastic waste streams.

This process involves three reactions: Hydroconversion, hydropyrolysis, and reforming. In integrating hydroconversion and hydropyrolysis, the plastic waste directly converts to liquid hydrocarbons. This process does not need an external supply of hydrogen, thus making this process more economically viable. This treatment technique eliminates the pretreatment requirement of waste sources and arises as a promising technology having overall economic potential and minimizing investment risk (Shell Global, n.d.; Laxmi Narasimhan and Del Paggion, 2016).

Catalytic pressure-less depolymerization

The catalytic pressure-less depolymerization method was first introduced by the German company Alphakat GmbH, proposing the direct conversion of the plastic waste source to liquid fuels at atmospheric pressure conditions. Compared with other technologies, the catalytic pressure-less depolymerization process removes oxygen atoms and makes the final yielded liquid fuel suitable for direct utilization in combustion engines. It can handle all types of waste sources from polymer plastics and their derivatives to lignocellulose. The mild operational parameter requirements makes this process more attractive compared with other technologies such as pyrolysis (Fakhrai and Saadatfar, 2015). According to the reports from Alphakat GmbH, this technology is ready for transfer to industrial and large-scale applications after a satisfactory performance during feasibility studies.

However, the feedstock needs to undergo pretreatment to reduce particle diameter to less than 3 mm and to reduce the moisture content to less than 5 wt%. The catalyst, shredded feedstock, and lime are mixed with a carrier oil and heated to a temperature of 180°C. The catalyst employed for the process is pure crystalline alkali-doped aluminum silicate; utilization of natural origin catalyst can replicate the natural process of oil formation on accelerated form (Wongmaha, 2018). Lime is added to obtain the optimum pH of 9 to carry out the catalytic reaction. The oil mixture is supplied over to turbine reactor, and the temperature is inclined to 250°C. Solid and liquid materials are dragged by high-speed rotation of turbine blades.

Due to the centrifugal force, the hydrocarbons get separated from other residues; the frictional and mixing energy leads to the rise of temperature, resulting in the deoxygenation and depolymerization of extracted hydrocarbons. Still, further studies need to be carried out to understand the chemistry behind the process. The by-product fuel consists of high sulfur content that fails to meet environmental regulations (Labeckas and Slavinskas, 2013). Various modifications in the design model need to be adopted to improve the quality of the derived fuel (Fig. 11).

Gasification

Gasification technology is widely used to convert the bulk waste materials ranging from biomass to plastic to hydrocarbon-rich syngas (CH_4 , H_2 , CO) through partial oxidation (Heidenreich and Foscolo, 2015; Ruiz *et al.*, 2013). This process needs an oxidation agent such as air; oxygen and steam are typically used. Air is the cheapest oxidation agent option regarding operational expenses but has several downsides such as more robust in segregation and high gas flow rate (Wilhelm *et al.*, 2001). In syngas, along with the presence of rich hydrocarbons, toxic contaminants are also present; new purification technologies need to be incorporated requires additional investments. Various valuable by-products such as methanol can be extracted through the methanol-to-olefins process, whereas the paraffinic hydrocarbons can be extracted via the methanol-to-gasoline process. The gasification of bulk plastic is possible for the production of syngas rich in hydrocarbons. However, further improvement in the design of the reactor is needed before considering bulk plastic as a feed source (Brems *et al.*, 2012).

Fig. 11 Schematic diagram for Texaco gasification process. Reproduced from Ragaert, K., Delva, L., Van Geem, K., 2017. Mechanical and chemical recycling of solid plastic waste. *Waste Management* 69, 24–58. doi:10.1016/j.wasman.2017.07.044.

Hydrolysis

Hydrolysis is a chemical recycling approach utilizing alkaline, acid, or neutral environmental conditions to depolymerize plastic waste sources into monomers. The main drawback of the hydrolysis process is the requirements of high-temperature ranges from 200°C to 250°C, pressure between 1.4 and 2 MPa, and an extended time duration to complete depolymerization. In alkaline hydrolysis solution, potassium hydroxide or sodium hydroxide were employed and were followed by hydrothermal treatment.

Similarly, an acid hydrolysis treatment of sulfuric acid and other minerals acids is commonly utilized for depolymerization. Whereas in neutral hydrolysis, steam or hot water at high pressure were used for the depolymerization (Al-Sabagh *et al.*, 2016). In all these hydrolysis techniques, neutral hydrolysis gained more attention as it is considered eco-friendly.

Biodegradation Method of Recycling

Biological treatment techniques have been applied to the recycling of plastic derived from bioresources. The biodegradable plastics are comparatively advantageous due to their eco-friendly nature and can act as a replacement of traditional plastics in specific environmental applications (Kale *et al.*, 2007). Biodegradable plastics composed of starch, cellulose, and biopolymers, which are consumed by microorganisms, ascribable to the enzymatic activities the molecular weights becomes reduced (Fig. 12).

Starch is another widely utilized biopolymer in plastic production due to its availability, biodegradability, and inexpensiveness (Chattopadhyay *et al.*, 2011). Starch consists of amylase and amylopectin polymers, making it an appropriate alternative. The starch-based polymers, which are further categorized as starch-based and starch-filled polymers, are mainly used in the packaging and manufacturing industries (Jayasekara *et al.*, 2005). Various microorganisms such as fungi, algae, and bacteria are commonly employed to decompose these polymers. Most of these microorganisms are sensitive to environmental conditions under both aerobic and anaerobic conditions (Shah *et al.*, 2014).

The most commonly utilized biodegradable plastics are polylactic acid or polylactide (PLA) and poly-hydroxyalkanoates (PHA) (Alaerts *et al.*, 2018). PHAs are a biodegradable polyester derived by bacterial fermentation of lipids and sugars. PHAs polyesters have been utilized for broad applications but are prominently used in the pharmaceutical, packaging, and medical industries (Kushwah *et al.*, 2016). As stated above, the environmental conditions play a vital role in the decomposition of PHAs. Most frequently employed bacterial genres are *Cupriavidus*, *Bacillus*, *Nocardiopsis*, and *Burkholderia*.

Fungal species, such as *Micromyces* and *Mycobacterium*, are utilized in PHAs decomposition (Boyandin *et al.*, 2013). PLA is extracted from plant resources like tapioca roots, cornstarch, and sugarcane. It has been widely employed for medical applications as it is safe for consumption (Ikada and Tsuji, 2000). Studies have shown that TPA can be replaced by biologically derived 2–5 furan dicarboxylic acid for the synthesis of highly efficient and high performing bioderived PET polymer. (PLA) is the most commonly used biodegradable polymer and is composed of lactic acid in corn. PLA has less toxicity, excellent mechanical properties, and suitability in biomedical and packaging applications. However, a significant drawback of PLA polymer is its poor thermal properties. PLA polymers usually degrade within 12 months, which prevents accumulation in the environment compared

Fig. 12 Various biodegradation pathways to treat plastics. Reproduced from Moharir, R.V., Kumar, S., 2018. Challenges associated with plastic waste disposal and allied microbial routes for its effective degradation: A comprehensive review. *Journal of Cleaner Production* 208, 65–76. doi:10.1016/J.JCLEPRO.2018.10.059.

with other plastics. LCA studies have shown that PLA polymers have less greenhouse gas emissions compared with petroleum-based plastics. PLA has good mechanical, biodegradability, and availability making it a suitable option for industrial and other applications (Liu *et al.*, 2000). The by-products of hydrolytic degradation of PLA can be easily decomposed by microorganisms such as *B. licheniformis*, *Cryptococcus* sp., *Amycolatopsis* sp., etc. (Fukushima *et al.*, 2009; Anderson and Shive, 2012).

Various industry sectors, like consumer electronics and automotive industries, have incorporated bioplastics in their products. PLA blends are successfully used in the manufacturing of monitor screens and other electronics peripherals such as headsets, tablets, cell phones, game consoles, and earphones (Research and Markets, 2018). Biobased polyester has also shown its footprints in the automobile industries with its superior characteristics such as high stiffness, preferable thermal shock resistance and electrical characteristics, and improved dimensional stability. Industry giants like Toyota and Rochling automotives have included bioplastics in their automobiles (Calza *et al.*, 2017). Poly(lactic-co-glycolic acid) is another classification of biodegradable plastic widely utilized in the food and drug delivery industries (Ashter, 2016) (Table 3).

Biodegradation of plastic using microbes

The production of extracellular enzymes assists microorganisms in the degradation of biopolymers into carbon dioxide and water through enzymatic and metabolic activities (Shah *et al.*, 2014). The catalytic activity of enzymes depends on the microbial species employed and even within the strains. The efficiency of degradation varies for different species and polymer types. For example, the fungi species is more suitable for biodecomposition of lignins composed of laccases to catalyze nonaromatic and aromatic compounds through oxidation (Mayer and Staples, 2002). The preliminary mechanism in plastic biodegradation is affixing of microorganisms with polymers by surface colonization. The enzyme hydrolysis of plastics consists of two stages: The initial stage is attaching of enzymes with polymers accompanied by hydrolytic division. The by-products of degraded polymers like dimers, monomers, and oligomers, which are low in molecular weight, get converted to water and carbon dioxide through mineralization (Tokiwa *et al.*, 2009). Under aerobic environmental conditions, bacteria utilize oxygen as electron acceptor followed by synthesis of organic compounds. As a result, water and carbon dioxide are produced as the end products (Priyanka and Archana, 2011). However, in anaerobic conditions, during the absence of oxygen, the polymers are broken down by microorganisms. The anaerobic bacteria utilize iron, nitrate, manganese, carbon dioxide, and sulfate as electron acceptors. New pathways and microbial enzymes need to be studied to further optimize the degradation of biopolymers more effectively.

Factors influencing plastic biodegradation

Various factors, including environmental degradation parameters and polymer and enzyme characteristics, play an instrumental role in microorganism activities. Moisture is one of the most crucial parameters that affect the multiplication and activities of microorganisms. Sufficient moisture is adequate for microorganism survival and for carrying out the hydrolysis process. Similarly, acidic and basic parameters can influence the rate of hydrolysis reactions. From various studies, a pH of 5 is optimal for the hydrolysis reactions (Auras *et al.*, 2004; Mohanty *et al.*, 2005). Similar to pH, the softening temperature is significant for enzymatic degradation. As the softening temperature increases, the possibility of biodegradation becomes limited. Polyesters with a high melting point are less appropriate to the biodegradability option (Tokiwa and Calabia, 2004).

Note: Moharir, R.V., Kumar, S., 2018. Challenges associated with plastic waste disposal and allied microbial routes for its effective degradation: A comprehensive review. *Journal of Cleaner Production* 208, 65–76. doi:10.1016/J.JCLEPRO.2018.10.059.

Different enzymes may have differently shaped active sites and, therefore, are more able to biodegrade certain polymers. For example, the fungal species *A. Niger* and *A. flavus* degraded straight chain polymers derived from diacid monomers quickly compared with other derived polymers (Kale *et al.*, 2007). The polymer characteristics such as shape, size, and molecular weight are also crucial parameters in biodegradability. The rate of degradation depends on molecular weight; at a high molecular weight above 4000, the rate of degradation is lower when compared with low molecular weight polymers (Kale *et al.*, 2007). Similarly, the polymer with larger surface area degrades much quicker

compared with one with a smaller surface area (Kijchavengkul and Auras, 2008). The presence of other additives such as dyes and toxic paints have an impact on the growth and overall activities of the microorganisms due to the presence of toxins (Yang *et al.*, 2005).

Challenges for Plastic Recycling

Bulk plastics usually exhibit weak mechanical properties due to inadequate interfacial adhesion. When bulk plastics are melted together, their entropy of mixing will be very low, leading to inefficient mixing and phase separation. The phase boundaries will be fragile in nature, and structural properties of the resulting compound will be very weak (Kutz, 2016). As a result, mixed plastics have minimal applications due to fewer returns. Most of the plastic recyclers focus on the single type of plastics so that their composition and properties can be identified easily and modification can be carried out to produce a recycled compound exhibiting the same properties as that of virgin plastics, ultimately bringing about great profitability (Merrington, 2017).

The presence of various additives, coatings, discoloring agents, antioxidants, and cross-contamination issues makes the recycling of plastic a tedious process (Hahladakis *et al.*, 2018). One of the significant challenges faced in the recycling of bulk plastics is that different types of plastics are not adaptable to each other at the atomic or subatomic level due to the inherent incapability of being mixed or blended (Hopewell *et al.*, 2009). For example, the presence of a PVC contaminant in the PET during the recycling process leads to the generation of HCl gas from PVC at a high-temperature condition. On the other hand, the presence of PET in a PVC recycling process generates a solid mass of undistributed crystalline PET, which will diminish the value of recycled plastic waste (Hopewell *et al.*, 2009). The recycled plastics from household waste (HW) showed higher contamination of metal concentrations such as (Cr, Zn, Ti, and Pb) compared with virgin plastics, which limits the quality and feasibility of using reprocessed plastics (Eriksen *et al.*, 2018).

The presence of chromium is identified in the recycled HW plastics at an average range of 14 and 24 mg/kg. This may be due to either the usage of additives during the postproduction phase of plastics or during the waste management process (Pivnenko *et al.*, 2015). Due to the inclusion of metal-based additives during plastics recycling and inadequacy in metal removal, there has been a build-up of metal contaminants further causing a severe threat to human life and to the environment (Pivnenko *et al.*, 2016). The exposure of waste plastics either to UV radiations or sunlight, which further undergo photooxidation process, will ultimately contaminate land and marine environments (Moharir and Kumar, 2018).

The global market for recycled plastics highly depends on the price of crude oil (Meng *et al.*, 2015). As the demand for petroleum products decreases, the demand for recycled plastics subsequently also decreases. This will automatically discourage prevailing plastic manufacturers from buying recycled plastic products (Triguero *et al.*, 2014). Recycling mixed plastics is a challenging process in PSW (García, 2016). The complexity occurs in separating residues from mixed plastics due to improper separation of blends, which will ultimately result in the generation of products with poor mechanical properties (Valavanidis, 2018). Another critical challenge is in identifying suitable plastic recycling technologies. The challenge is imposed in treating a large number of bulk plastics within minimal expenditure and fewer maintenance costs. This method has the potential of being used as a substitute for landfilling or incineration, which are known to be less eco-friendly (Jacob-Vaillancourt and Sorelli, 2018). Since plastics are a recalcitrant polymers, they will not degrade easily by natural means and they show high persistence in nature, which is usually, on average, about 100 years (Alam, 2015). Hence, proper monitoring of recycled plastics must be carried out. Additionally, the identification of efficient PWM technologies and absence of contaminations before usage should also be present.

Properties of Recycled Plastics

It is crucial to understand the characteristics of the recycled plastic for determining its suitability in various applications. After the initial life cycle or repeated usage of plastics, the used plastics can be recovered or recycled into new products. Since the recycled plastic obtained from diverse sources has been exposed to distinctive conditions, the plastic materials also exhibit distinctive degradation and performance characteristics (Merrington, 2017). The recovered plastic is categorized by its mechanical and chemical characteristics for its further application.

The plastic degradation is complex; the degradation process can primarily be categorized as either biological, mechanical, chemical, thermal, or a combination of more than one process, for example, thermomechanical, thermooxidative degradation, etc. The degradation process could exhaust inherited properties. However, in some rare cases, the properties of the recycled plastic are identical to those of virgin plastic (Najafi, 2013). There are several crucial factors that play a vital role in the recycling of plastic; such factors are discussed in the following sections.

Melting Point

The melting points of different plastic sources are listed in Table 4. Most of the plastic sources have a melting point below 200°C; however, the plastic sources containing additives and impurities have melting points above 200°C (Biron, 2017).

The melting point becomes decisive when plastic sources are composed of distinctive polymers with different melting point temperatures. In such cases, the identification of the optimal melting point is challenging. The plastic sources with lower melting point melt quickly compared with other sources having a higher melting point; as a result, the final product becomes

Table 4 List out the melting points of various commonly used plastics

<i>Plastic sources</i>	<i>Melting point (°C)</i>
Polyethylene terephthalate	245
Polystyrene	240
Polyamide 6	233
Mixed plastics	185
Polypropylene	170
Polyethylene	135
High-density polyethylene	130
Linear low-density polyethylene	123
Low-density polyethylene	115

heterogeneous. In further detail, the plastic sources consist of PP and LDPE. The melting point of LDPE is 115°C, whereas the PP has a melting point of 170°C. If the melting process has been processed to suit for the LDPE, then the unmelted PP results in defects in the final heterogeneous product (Goodship, 2007).

Furthermore, the melting of LDPE leads to impairing the mechanical characteristics of the resultant plastic. It is necessary to identify the optimum melting point of mixed plastic sources, and it can be attained by performing further experimental investigations.

Immiscibility

The segregation of recycled plastics from one another demands additional burdens. A significant burden is that of finances; therefore, it is preferable to use recycled plastics as fused. The polymer blending approach is utilized to overcome fundamental drawbacks such as low impact strength on plastics and also cut down the final production cost. The major drawback in mixing plastics is that the majority of the polymers are immiscible. The weaker physical attraction occurs at phase boundaries of immiscible blends; this could cause phase separation under stress, leading to evolving materials with poor mechanical characteristics (Chanda and Roy, 2007).

The deficiency incompatibility between polymers in blending affects the quality of the recycled plastic products. The most effective technique to enhance the compatibility between plastics is to employ the compatibilizing agents. These agents have the ability to enhance the interfacial adhesion between polymers. A compatibilizing agent dosage of 2% to 5% can be added during the reprocessing stage. However, the cost and separation processing cost raise questions as to its economic benefits.

Rheology

The melt flow index is another crucial parameter for assessing the molecular weight distribution of the plastics. The plastic sources with higher melt flow index consist of shorter chains, resulting in a lower molecular weight, which makes for easier flow. Similarly, the lower melt index indicates a high molecular weight and longer chain. The increase of molecular weight boosts impact strength. Additionally, melt viscosity also results due to lower hardness, yield strength, softening point, and stiffness (Guerreiro *et al.*, 2012). Numerous investigations have been reported on modification of plastic's rheological properties especially on the decrease of melt viscosity after repetitive injection and extrusion molding (Gere and Czigany, 2018; Li *et al.*, 2018; Wang *et al.*, 2016; Zhao *et al.*, 2018; Záleská *et al.*, 2018). During the processing of virgin plastic to other value products, the antioxidant is diminished due to excessive shearing and overheating. As a result of limited availability of antioxidants, depolymerization will occur (Najafi, 2013).

Due to the extrusion process, polymer degradation occurs due to severe stress and the thermal cycle leads to further declination in molecular weight. Antioxidants can result in slow thermomechanical degradation that results in the final product characteristics. Recycled PP tends to undergo degradation more efficiently than virgin plastics, and its recycling is followed by a reduction in melt index (Takatori, 2015). PP is more sensitive to oxidation and requires a higher concentration of antioxidants. The antioxidants aid in preserving properties of plastic at higher temperature shielding the recycled plastics from rapid degradation under direct air, oxygen, direct sunlight, pollutants, water, and other elements.

The presence of foreign matter would contaminate and ultimately decrease the impact strength of recycled plastic material (Takatori, 2015). The major drawback in using recycled PP is the reduction in mechanical strength due to the diminished number of tie molecules associated with the lamellar layer of recycled PP in contrast with virgin PP (Takatori *et al.*, 2016; Tominaga *et al.*, 2015).

Cross-Linking

The cross-linking mechanism is used to enhance the thermal properties of thermoplastics for a wide variety of applications by means irradiation with heat, UV, X-rays, or gamma radiation (Mizera *et al.*, 2012). Cross-linking helps in increasing impact strength, creep resistance by reducing crystallinity, melt flow index, and break at elongation (Najafi, 2013). Heavy cross-linking restricts the movement of molecular chains, resulting in a break in the continuity of melt flow, which ultimately changes the nature of the polymer to thermoset from thermoplastic (Maitra and Shukla, 2014).

Cross-linked polymers are used in a wide variety of application, including medical, pharmaceuticals, biomedical fields, hot pipes, solid phase extraction, paper coating, synthesizing a stronger antiviral biocide, and so on (Mane *et al.*, 2016; Hongbo *et al.*, 2016; Parhi, 2017). Recently, cross-linked polyethylene waste has been used as a modification of binder. Additionally, aggregates for asphalt mixtures were found to be useful and enhanced in the performance of road pavement applications (Costa *et al.*, 2017).

Crystallinity

The crystalline nature of thermoplastics is characterized by a thick-packed arrangement of molecular chains, hardness, resistance to heat, and rigid in structure compared with other types of polymers (Grigore, 2017). Examples of such polymers are LDPE, PP, and HDPE (Mark, 2017). An irregular arrangement of molecular chains characterizes the amorphous nature of thermoplastics. Examples include PVC, PS, and polycarbonate. The semicrystalline nature of polymers is exhibited by combined properties of crystalline and amorphous polymers and characterized by nearly ordered molecular chains (John, 2017). Examples include polyamide imide and polyester poly-butylene terephthalate.

Recycled plastics show less crystalline nature compared with virgin plastics (Yao *et al.*, 2013). PP is an economically viable thermoplastic polymer showing crystalline properties of about 40%–60%. PP is characterized by low density, high melting point, and excellent resistance to higher temperature. PP is characterized by low density, high melting point, excellent resistance to higher temperature and impacts, and better recyclability compared with other thermoplastics and applicability in electrical cable insulation, medical, and automobile sectors (Maddah, 2016).

Polarity

The formation of polar side groups makes the polymer chains stronger through strong hydrogen bonding. Thermopolymers such as PP and PE have a shallow surface free energy and polarity and are used for developing wood plastic composite (Najafi, 2013). In recycled plastics, the presence of polar groups enhances the affinity between polar lignocellulose and nonpolar plastic materials (Karumuri *et al.*, 2017). Oxidized polyolefin is used as a superior compatibilizing agent for plastics to enhance adhesiveness between nonpolar and polar matrices (Ugbolue, 2017). The compatibilizer mainly consists of maleic anhydride or carboxylic acid-functionalized ethylene copolymer (Kaiser *et al.*, 2017). During the oxidation process, a substantial amount of oxygen is assimilated into the polymer in the form of carboxyl, aldehyde, hydroxyl, ketone, and ester groups (Gewert *et al.*, 2015). It is shown that oxidized PP exhibited a better enhancement in mechanical and physical properties of wood–PP composite and was found to be more effective than maleic anhydride embedded PP (Peerbooms and Pickering, 2018).

Applications of Recycled Plastics

Recycled plastics have shown a wide variety of applications in various fields such as construction, the automobile industry, and in food packaging (Goodship, 2007). The uses of recycled plastics in various fields of applications are listed in Table 5.

Environmental Aspects of Recycled Plastics

Recycling of bulk plastics is one of the most effective methods in mitigating environmental impact and resource exhaustion (Emily and North, 2013). There are a lot of environmental benefits in using recycled plastics. Recycling of plastics aids in the preservation of petroleum resources, decreasing greenhouse gases and CO₂ emissions and limiting landfill waste contamination (Shrivastava, 2018). Waste plastic bottles can be reused and refilled, and used as storage containers (Intertek, n.d.). Recycled plastics preserve fossil usages, which are needed for synthesizing virgin plastic materials (Biron, 2017). The advantages of recycled plastics include a reduction in global warming, minimizing waste disposal in landfills, preventing air and water pollution, and conserving energy and natural resources (Richards, 2014; Soffar, 2016).

According to the Environmental Protection Agency recycling 1 pound of PET plastic waste can preserve heat energy, which aids in decreasing the damage and overload of power grids (Balakrishnan and Flora, 2017). The use of recycled plastic concrete helped in the abatement of the carbon footprint by about 15.3% and reduction of consumption of overall energy by 16.2% (Betita, 2013). However, some drawbacks include the generation of toxic volatile organic compounds gases during plastic recycling. The generation of pollutants is a drawback in assuring quality recycled products. Additionally, improper recycling procedures result in adverse environmental impacts (Hartman, 2017). For example, the recycling of PVC is quite challenging due to the presence of VCM (vinyl chloride monomer). VCM has the chemical property to break down and release chlorine components, which ultimately results in the accumulation of dioxins, a toxin, in the environment (Zhang *et al.*, 2015). Hence the quality and feasibility of using recycled plastics require better evaluation.

Table 5 Application of various recycled bulk plastics

<i>Types of plastics</i>	<i>Field of application</i>	<i>References</i>
Polyvinyl chloride	Packaging material for drinking bottle, clothes, food and medical purposes, wallpaper, coatings, construction purposes, plastic composite.	(Thakur, 2015; Petrović and Hamer, 2018; Mamoor <i>et al.</i> , 2013; Arjmandi <i>et al.</i> , 2015)
Polyethylene terephthalate	Concrete, carpet fibers, drinking and detergent bottles and polyester fiber, used as an additive in the construction of roads, water filtration, plastic cement, packaging, construction applications, 3D printing filaments.	(Gu and Ozbakkaloglu, 2016; Singh <i>et al.</i> , 2017; Zander <i>et al.</i> , 2016; Jassim, 2017; Pechyen, 2017; Bolduc <i>et al.</i> , 2018; Evans <i>et al.</i> , 2016)
High-density polyethylene	Laundry detergent bottles, mobile parts, pipes used for agricultural purposes, films, toys, and floor tiles, flat roofs, 3-D printing filaments.	(Rahimi and Garcíá, 2017; Smolka and Sobotka, 2018; Kamaruddin <i>et al.</i> , 2017; King <i>et al.</i> , 2014)
Low-density polyethylene	Agricultural plastic films, composite in rubber, composite in plastic application.	(Picuno <i>et al.</i> , 2012; Kaewduang <i>et al.</i> , 2015; Lim <i>et al.</i> , 2016)
Polyamide	Enhancement in melt flow index and elasticity modulus of waste silk, prevents greenhouse gas emissions, consumer goods, transport, industrial applications.	(Taşdemir <i>et al.</i> , 2013; Pelin <i>et al.</i> , 2017; Singh <i>et al.</i> , 2018)
Polycarbonate	CDs, audio, video, medical equipment, purification membranes, safety glasses, automobile sector, compatibilizer.	(Jones <i>et al.</i> , 2016; Antonakou and Achilias, 2013; Ramesh <i>et al.</i> , 2014)
Polypropylene	Appliances, automobile, construction of roads, enhanced properties of textile fiber, plastic bricks.	(Matei <i>et al.</i> , 2017; Appiah <i>et al.</i> , 2017; Araujo and Morales, 2018; Bredenoord, 2017)
Polystyrene	Geopolymer encapsulation, lightweight concrete for building applications, packaging, insulation, conserve natural resources.	(Makai <i>et al.</i> , 2015; Schlummer <i>et al.</i> , 2017; Castro <i>et al.</i> , 2017)
Mixed recycled plastics	Fencing, seating, bridge components, pilings, railings, military load bearing, and civil applications, a replacement for asphalt mixtures in pavement applications.	(Bajracharya <i>et al.</i> , 2014; Lee <i>et al.</i> , 2012; Zakaria <i>et al.</i> , 2018)

LCA and economic methods are used for evaluating the environmental aspects of PWM. The reports showed that the recycling mechanism showed the least environmental effects on total energy use and global warming (Bernardo *et al.*, 2016). Recently, the environmental aspect of recycling waste electrical and electronic equipment (WEEE) plastic was evaluated by LCA analysis in Brazil (Campolina *et al.*, 2017). The reports showed that the recycling of WEEE plastics resulted in the reduction of environmental effects by up to 4 times compared with incineration methods and up to 6–10 times lower when compared with the generation of virgin plastics (Wäger and Hischer, 2015). The recovery of WEEE plastics resulted in a reduction in energy needs, consumption of raw materials, and environmental impacts (Biganzoli *et al.*, 2015; Milios *et al.*, 2018).

Conclusion

Recycling of bulk plastics is the most commonly used mechanism to combat the intensifying plastic waste contamination. The ultimate aim is to implement a plastic economy where the waste plastic products are 100% recyclable, and are used for long-term applications with less environmental impact. The recycling advancements are the molecular level, the emergence of new initiatives, and support from governments and manufacturers have helped to achieve greater targets and accomplished changes in the recycling sector. Recycling of waste plastics requires high energy needs, which finally produces low-quality recycled polymers exhibiting low chemical and thermal properties. The presorting step before recycling is highly time-consuming and expensive in nature. Prevailing technologies cannot be used in recycling all plastic waste. At present, there are no effective low-energy segregation methods for mixed plastic polymers and packaging in mechanical recycling. Hence, further development is required. The presence of cross-linked polymers in elastomers and thermosets is not well adaptable to current mechanical recycling techniques. Studies have to be carried out to identify suitable polymers in which cross-linking undergoes reversal or exchange at high-temperature conditions, which further facilitates the remaking of the polymers before reusing. Recent research is focused on chemical recycling, which requires low energy, improved compatibilization of mixed plastic waste to avoid the presorting needs, and enhanced recycling apart from thermoplastics. The presence of better compatibilizing agents helps to regulate the phase behavior of polymer mixtures and reduce the contamination issues associated with mixed plastics without losing properties of recycled materials.

Another emerging area in plastic recycling is synthesizing biodegradable plastics, which can replace prevailing conventional plastics. Biodegradable polymers are more accessible to degrade by the action of microorganisms under oxygen-rich and deficient conditions, oxidation, or photodegradation. Biobased polymers have an exciting future in synthesizing highly efficient polymers. In the future, to make efficient recycling to a genuinely new recycling, approaches have yet to be identified by seeking support from the governmental, research, and industrial sectors and creating awareness of the public about the need for and benefit of recycling plastics. Developing advanced computational modeling, identifying new compatibilizing agents, and synthesizing novel polymers will help in upgrading recycling mechanisms, which will be very helpful in the future.

The Potential of Core-Shell Technique in the Enhancement of Different Derived Calcium Carbonate Wastes in Anticorrosive Paints

NM Ahmed, WM Abd El-Gawad, and MG Mohamed, National Research Centre, Cairo, Egypt

© 2020 Elsevier Inc. All rights reserved.

Introduction

Waste management constitutes one of the world's main problems in our recent times due to its tremendous economic and social impact. The concern about solid wastes is increasingly growing because of the serious problems they can implement to the environment and the negative conditions to health and economic loss they can cause. Moreover, the rapid economic growth, climate change, resource depletion and the exploitation of natural resources have forefront the problem of waste management rapidly towards more studies on their reusability in different useful industries that are beneficial to daily human life services and not being a burden (Xiaoa *et al.*, 2018).

Although reusing waste materials is not a new issue particularly in the industrial sector, the appropriate waste management is one of the main requisites for sustainable development to guarantee suitable utilization of wastes according to their types, chemical structure and properties. Numbers of small and large enterprises have emerged in response, aiming at recycling and adding commercial value to the waste materials that can help to diversify production and reduce final costs, in addition to providing alternative raw materials for number of industrial sectors. Overlooking was extended to the fact that some wastes are similar in their composition to the natural raw materials used nowadays, and often contain materials that are not only compatible but also can be helpful in the fabrication of other new materials. Within this scenario, upgrading industrial wastes to alternative raw materials became interesting both technically and economically for a wide range of applications (Awasthi and Li, 2017).

Stone industry is an important one in the worldwide economy; it produces huge amounts of residues with different dimension and particle sizes (Marras *et al.*, 2010). Marble is one of the largest produced natural stone in the world and it accounts for 50% of world's natural stone production. It is crystalline metamorphic limestone, basically containing calcite (CaCO_3) and dolomite $\text{CaMg}(\text{CO}_3)_2$. The process of quarrying marble stones is performed in order to produce slabs and tiles, which are widely used in the construction industry for high quality flooring and wall cladding purposes. In the process of converting in-situ stone deposits to the final product, significant amount of waste is generated in both the mine site, and in the processing and polishing plant. These wastes are generated in the form of fragments and shapeless blocks which have no commercial value. Marble wastes produced in the quarrying and cutting processes of ornamental stones is becoming a worrying factor for both industry owners and environmentalists due to the growing amount of these rejected waste materials (Almeida *et al.*, 2007; Yeşilaya *et al.*, 2017).

Food industry also generates a lot of biological wastes which release many problems due to their disposal cost and landfill problems. However, there is an opportunity for the bio-economy society to use these residual materials in new applications, and it definitely deserves the attention of the scientific world. Eggshells are unique natural biomaterial with fascinating structures, which offers rich plethora of utilizing possibilities that can be broadened by further treatment. In recent years, great efforts are conducted for the application of eggshells as value added products (Mittal *et al.*, 2016).

Eggshells are comprised of protein fibers network, associated with crystals of calcium carbonate (96% of shell weight), magnesium carbonate (1%), calcium phosphate (1%) and also some organic materials and water. Calcium carbonate (CaCO_3) which is the major constituent of the eggshell is an amorphous crystal that occurs naturally in the form of calcite (hexagonal crystal) with low water solubility (Baláz, 2018).

Both marble and eggshells are considered as resources of calcium carbonate which have diverse uses such as employing it in the construction industry, either as a building material or limestone aggregate for road building or as an ingredient of cement or starting material for the preparation of builder's lime by burning in a kiln. Also it is widely used as an extender in paints and has traditionally been a major component of blackboard chalk, also it can be used in the production of glossy paper (Wahab, 2017).

Concerning the wastes; many attempts were made to incorporate marble wastes into raw material mixtures in order to produce different products, besides its usage as reinforcement or raw material in various areas and applications. In the construction materials sector, many researchers have studied the production of concrete with varying percentage of marble waste to replace the cement in order to enhance the concrete characteristics (Shelke *et al.*, 2012). There are also other studies investigating the reusability of marble wastes in the concrete as aggregates because of its lower water absorption compared to other natural aggregates, which can achieve improvements in the water absorption, abrasion and porosity values of the concrete whereas decreased flexural and pull-off strengths (Binici *et al.*, 2007).

Many uses have been studied also for beneficiation from the eggshells waste which is a rich source of minerals that can serve as a pharmaceutical excipient and base material for developing medicinal, dental preparations, food additive and calcium

supplement; diluent of solid dosage forms, agricultural fertilizer component, and as a component for bone implantation (Oliveira *et al.*, 2013).

New Evolving Preparation Technologies

The development of different chemical preparation techniques have become an integral research area due to the potential changes they cause in the different compounds. In planning the route of chemical synthesis, researchers usually visualize the end product, fore fronting the search toward increasingly simpler methods. Nowadays, new technologies facilitate the usage of modified plan routes for synthesizing particles with different sizes, shapes and surface morphology. The goal in developing new chemical techniques is to find how to manage the reactions of the different materials to produce new tailored materials that are capable of promoting some desired properties that can be useful in the different strategic industries. These tailored materials will lead to locomotive development of new chemical synthesis methods providing an opportunity to offer specific properties for a wide range of desired applications.

Core-shell particles have attracted considerable interest as a class of new materials with diverse applications due to their various advantages, such as low cost and ease of preparation. Core-shell technology has become an important research area since few decades, offering particles of biphasic materials with an inner core and an outer shell that are of different compositions. The core-shell materials may be of different sizes and shapes, i.e., nano shell/micronized core and vice versa or both of the same sizes. These particles contain different materials depositing on each other, and covering the cores even with thin shell of another material can bring many new properties to the formed particles including; promoted reactivity, thermal stability, or oxidative stability, etc. (Ahmed, 2009; Xiong *et al.*, 2006).

Corrosion Causes and Rehabilitation

Corrosion is a naturally occurring phenomenon and just like all natural processes, it is spontaneous and can drive the materials to its lowest possible energy states. Most of the metals and alloys have natural tendency to combine with water and oxygen present in their environment and return them to the most stable state, i.e., their native and stable oxide states (Revie and Uhlig, 2008).

Corrosion can result in dangerous and expensive damage to everything starting from home appliances, till bridges and buildings. It has many effects in our daily lives, a direct one in affecting the useful service lives of our possessions, and an indirect one that concern the producers and suppliers of goods and services which incur corrosion costs that they pass on to consumers. Corrosion can cause serious consequences on people lives, as in corrosion of steel reinforcing bar (rebar) in concrete which can proceed out of sight and suddenly result in failure of; a section of highway, collapse of electrical towers, damage to buildings, parking structures, and bridges, etc., resulting in significant repair costs and endangering public safety (Pour-Ali *et al.*, 2015).

The major cost and consequences of corrosion can be represented in three points;

- Affecting the national income because they can cause financial expensive loses.
- Waste of natural resources.
- Inconveniences and injuries to human beings and sometimes even loss of life.

Corrosion also takes place in different ways and it can be classified according to one of these three factors;

- Nature of the corroding materials; this classification is based on the condition of corrosion either “wet” or “dry”. The presence of moisture is essential for both methods which usually involves reaction with gases at high temperatures.
- Mechanism of corrosion; corrosion can occur either electrochemically or with direct chemical reactions.
- Appearance of the corroded metal; corrosion can be either uniform where the metal corrodes at the same rate over the entire surface, or localized when only small areas are affected.

Although corrosion is a natural process, it can be controlled by using effective methods and strategies including main five primary ways to control corrosion; materials selection and design, cathodic and anodic protection, inhibitors and coating.

The most generally used method for corrosion prevention is protective coatings. Their main function is providing satisfactory barrier between the metal and its environment (Mathiazhagan and Joseph, 2011).

A typical coating can offer many characteristics; aesthetic appearance, corrosion control, good adhesion, and abrasion resistance. The functioning of any protective coating is based upon three basic mechanisms;

- Barrier protection
- Chemical inhibition
- Galvanic (sacrificial) protection

In order to provide maximum protection, a protective coating should provide different functions mainly in;

- (1) Resisting the penetration of ions from salts that are in contact with the coating,
- (2) Minimize the action of osmosis,
- (3) Expanding and contracting with the underlying metal surface,
- (4) Retaining the aesthetic appearance over long period of time.

The major challenge that is facing the coatings industry during the last 40 years is the adoption of new coating materials, due to the depletion of natural resources that were used as pigments and additives. This challenge provides a great chance for reusing waste to be exploited providing new materials that are based on wastes which can be utilized in the coating industry to convert the wastes to useful materials that suit this huge industry. Therefore, appropriate and modern techniques must be utilized to produce modified waste materials with high efficiency and low cost.

Mixed Core-Shell Pigments

Pigments have very special place in the paints industry. They are the coloring elements present in paints, besides offering other main functions that lie in; hiding the substrates, providing color, modifying application properties and performance and/or reduce cost. Some of them can be classified as "functional" including specialty pigments, which can be used in broad array of coatings that can be used in a variety of applications.

Mixed pigments are novel category aiming to combine different metal oxides together in one compound with specific design and structure. The aim of developing these pigment mixtures is to enhance their efficiency and shift their characteristics to meet diverse applications to provide multifunctional roles by performing simultaneous multiple functions (Buxbaum and Pfaff, 2005).

Core-shell technology can participate in preparing new trends of mixed pigments to serve as multi-functional pigments in organic coatings. The prepared core-shell mixed pigments in this work will be based on core of different waste materials (marble and eggshells) covered with thin shell of known active pigment in anticorrosive performance. The produced particles are proposed to offer new characteristics gathering both the properties of core and shell together.

The shell will be composed of cobalt.zinc binary oxide which is considered as one of the most common multifunctional green pigments, due to its high mechanical resistance, high thermal and chemical stability, and low temperature sinterability besides offering intense green hues. They are usually synthesized at high temperature via solid-solid interaction between the two oxides, which is based on the mutual suppressing of the non-stoichiometry of the crystal lattices of ZnO and CoO, with relatively low content of CoO with respect to ZnO. Solid solution is easy to operate and does not introduce impurities (Ahmed, 2013).

CoO·ZnO binary oxide will be the shell precipitated on both marble (M) and eggshells (ES) wastes using core-shell technique to form CoO·ZnO/M and CoO·ZnO/ES core-shell pigments. The main advantage of using the core-shell technique in preparation lie in offering new enhanced properties which are different from its individuals and by choosing the suitable components the drawbacks and deficiencies of the individual components can be overcome.

For example, it is well known that cobalt is commonly used as drier, and this is a disadvantage of cobalt.zinc oxide green pigment which causes rapid curing, skinning and wrinkling of coated film, besides reduced water resistance on their use with excessive amounts in coating systems. The new pigments contain only thin shell of CoO·ZnO with low cobalt oxide content not exceeding 20%–30% of the formed compound, i.e., this low CoO content will not affect the curing time because it is now present only in very low concentration making the new core-shell pigments capable of offering better curing time without affecting the film properties or causing defects.

In this work, the new core-shell pigments will be integrated in anticorrosive coating formulations to serve in protecting steel structures exposed to marine environment and for the protection of reinforced concrete steel from corrosion damages.

Materials and Methods

Materials

- Marble waste is obtained as large pieces from working factories in Shaq El-Tho'aban area, then they were ground to fine particles using steel disk mill. After that, the ground powders were subjected to sieving process.
- Eggshells waste is collected and the organic membrane is removed, washed thoroughly with tap water, then it was dried at 80°C for 2 h. Crushing and grinding were the last steps of its preparation.
- All of the employed pigments, extenders, resins, solvents and additives are of normal chemical grades and are products of different local and international companies.
- The cement used in the preparation of concrete mix is CEM I type ordinary Portland cement.

Methods

Preparation of core-shell pigments

Three core-shell pigments were prepared; by the mixing of zinc and cobalt nitrates with eggshells and marble wastes via solid-solid interaction, i.e., grinding the solids with each other very well to be homogeneously distributed in each other, and then the mixture was calcined at 900°C.

Instrumental analysis

- X-ray fluorescence

The different concentrations of each element oxide in the different compounds were determined using Axios, sequential WD-XRF spectrometer, PANalytical 2005, USA.

- X-ray diffraction

X-ray powder diffraction patterns were obtained at room temperature using a Philips diffractometer (Model PW 1390) Japan, employing Ni-filtered Cu $K\alpha$ radiation ($\lambda = 1.5404 \text{ \AA}$). The diffraction angle (2θ) was scanned at a rate of $2^\circ/\text{min}$.

- Transmission electron microscope (TEM)

The different materials were examined using (JEOL JX 1230) technique with micro-analyzer electron probe (Japan). This technique shows a cross-section of the particles and determines the particle sizes of the different calcium carbonate sources.

- Scanning electron microscope/Energy dispersive x-ray analysis (SEM/EDAX)

Energy-dispersive X-ray analysis technique and scanning electron microscopy (JEOL JX 2840) micro-analyzer electron probe (Japan) was used in this work to estimate the particle shapes and determine the core and shell composition by showing the elements present on the surface of the formed compound.

Physical properties of the prepared pigments

The prepared pigments were evaluated according to international standard testing methods for specific gravity (ASTM D5965-02, 2013) and oil absorption (ASTM D 281-12, 2016).

Paint formulations

Epoxy resin is used in paint formulations because of many reasons that foster its use; the high adhesion related to the high polarity in its chain due to the presence of aliphatic hydroxyl and ether groups, and the strong electromagnetic attraction between the epoxy and the metal oxides found in the steel composition. Finally, the formation of chemical bonds between active hydrogen on the steel surface and epoxide groups in the coating which causes improved coating adhesion.

Also, it can participate in the anticorrosive action through the reduction of the corrosion of the metallic substrate by providing high cross-linking density, high barrier properties and also providing an effective physical barrier between the metal and the environment containing the aggressive species, such as an enhanced chloride ion concentration, O_2 or H^+ . They also serve as a reservoir for corrosion inhibitors that help the steel surface to resist attack from aggressive species.

Also, Epoxy resin represents a binder containing considerable amount of hydroxyl groups in its molecule, such groups can take part in corrosion reactions as inhibitors. Furthermore, prepared pigments are not typically evident on the surfaces, showing that they can be primarily embedded in the epoxy matrix and probably can be oriented parallel to the coating surface.

For all the previous reasons the paint formulations in this work are based on epoxy resin. Two groups containing four mixes were prepared with pigment/binder ratio P/B = 2 and pigment loadings 15 and 25 wt% of the whole solid content of the paints, these formulations are represented in Table 1.

Table 1 Paint formulations

Applications in Marine Paints

Preparation of steel coupons for corrosion testing of marine paints

Carbon steel coupons 8×10 cm were used for the corrosion testing, they were first cleaned using clean lint-less cloth wet with mineral spirits, then vigorous rubbing of the panel surface was done until all soluble and loosely adhering soil were removed. After that, the steel coupons were flushed with clean solvent and dried at a temperature of $52\text{--}93^\circ\text{C}$ before use. The paints were prepared employing ball mill and then they were applied on the previously prepared mild steel panels via film applicator to give a dry paint film thickness of $120\text{--}150\text{ }\mu\text{m}$.

Corrosion tests

(1) Accelerated laboratory test

Accelerated lab test was performed by applying X scribe of 1 mm width to the coatings along the panel to expose the underlying metal to the aggressive environment. After 28 days of exposure the panels were evaluated for;

- Degree of rusting (ASTM D610-08, 2012).
- Degree of coating adhesion by means of a cross-cut test (ASTM D3359-17, 2017).
- Degree of blistering on painted steel surfaces according to ASTM D714-02 (2017).
- Filiform corrosion resistance test photographic inspection was done according to ASTM D2803-09 (2015).

(2) Electrochemical impedance measurements

The corrosion protection performance of coatings was investigated using EIS (SP-150), which is obtained from biologic science instruments, France. The reference electrode was silver/silver chloride electrode, and the auxiliary electrode was a platinum sheet. The used electrolyte was 3.5% NaCl solution, EIS measurements were carried out by applying 10 mV sinusoidal potential through a frequency domain from 35 kHz down to 100 MHz. All the experiments were carried out in an aerated solution at room temperature. Coated steel coupons of dimensions (2×1 cm) were considered as the working electrode. The measurements were taken at different interval periods against immersion time to study the corrosion protection behavior. The obtained data were analyzed and fitted according to simple circuit showed in Fig. 1.

Mechanical properties of marine paints

The physico-mechanical properties that figure out the flexibility, elasticity and strength of the paint film were tested according to following standards;

- Hardness of the paints using the pendulum apparatus was done to study the film elasticity (ASTM D4366-16, 2016).
- Impact resistance (ASTM D6905-03, 2012); the test reveals the height of the free fall of a weight (1000 gm) at which the paint film still resists impairment, the test was performed on the reverse of the panel with a coating.
- The resistance of the coating against cupping in Erichsen cupping tester (ASTM D 5638-00, 2013), the objective of this test is to identify the resistance of the paint film against distortion of a coated steel panel with a pressed-in 20 mm steel ball. The result of the test deduces cupping in mm with the first disturbance of the coating.

Applications in Concrete

Preparation of concrete specimens and mix design

(1) Reinforced bars preparation

Plain steel rebars with 6 mm diameter were prepared using emery papers to remove materials like mill scales, grease, rust, oil, and dirt. The steel rebars were then flushed with clean solvent and dried. Then, the rebars were coated by brush to reach dry film thickness about $100\text{--}150\text{ }\mu\text{m}$.

Fig. 1 Equivalent circuit for fitting EIS data.

(2) Concrete preparation and mix design

Concrete mix is prepared and cured according to [ASTM C 192/C 192M-06 \(2006\)](#) as cubes with diameter $5 \times 5 \times 5$ cm containing embedded coated rebars, the mixing proportions is given in [Table 2](#).

Corrosion test for reinforced concrete cubes

The reinforced concrete cubes were totally immersed in the artificial sea water for 28 days and each cube was placed in a separated cell for the electrochemical measurements.

Bond strength (Pull out test)

This test is performed to determine the effect of the coating materials on the adherence between the steel rebar and concrete, a concrete cylinder of 600 mm height and 150 mm diameter containing an embedded coated deformed steel bar at its center was tested by a hydrodynamic equipment in which the mounted concrete was fixed, whilst the outer part of the rebar was connected to the driving holder. This driving holder was then moved and the ultimate force required to pull the rebar off was recorded.

Results and Discussion**Characterizations of Core-Shell Pigments****X-ray fluorescence (XRF)**

X-ray fluorescence is a powerful technique that can determine the elements concentration in the whole compound. The results in [Table 3](#) showed that, with regard to loss of ignition (LOI) both marble (M) and eggshells (ES) contain calcium oxide as a major content with percentage of 95%–98%. While in the prepared core-shell pigments, there was a decrease in this percentage due to precipitating the shell on its surface, which replaced some of the calcium carbonate, beside a rise in the concentration of both cobalt and zinc oxides representing the shell. Moreover, zinc oxide appeared with higher concentration than cobalt oxide revealing that cobalt concentration is very low compared to that of zinc oxide.

Table 2 Mix design for concrete (W/C = 0.6)

Materials	Mix proportions (kg/m ³)
Ordinary Portland cement (OPC)	405
Sand	750
Aggregate	843
Water	243

X-ray diffraction (XRD)

XRD results shown in Fig. 2 clarified that the dominant phase of calcium carbonate in both marble and egg shell is calcite with its main peak at 2θ 30 according to JCPDS Card No. 05-0586. On the other hand, the patterns of the prepared core-shell materials showed more crystallinity than marble and eggshells, which is clear in the appearance of extra peaks at 2θ 31.9, 34.1, 34.3, 36.2, 47.2 and 49.5 representing zinc and cobalt oxides which form the shell revealing the formation of new phases that were not present in marble or eggshells individually, confirming the formation of a new compound.

Fig. 2 XRD of the different wastes and the core-shell pigments.

a. Marble (M)

b. CoO.ZnO/M

c. Eggshells (ES)

d. CoO.ZnO/ES

Fig. 3 TEM photos of the different wastes and the core-shell pigments.

Morphology of the particles

Figs. 3 and **4** representing the TEM and SEM photos of marble and eggshells showed the presence of the rhombohedral forms of calcium carbonate as large plate structures once as separated particles in case of marble and other as aggregates in case of egg shell.

In case of core-shell particles, these rhombohedral plates were covered with stuck particles on their surface representing the shell layer, these particles cannot be separated looking like-welded to each other in one compound.

Energy dispersive X-ray analysis (EDAX)

EDAX analysis is one of the main tools to prove the presence of the shell elements because it shows the elements on surface up to 1 μ depth. The charts in **Fig. 5** and the related tables cleared that zinc is present in higher percentage than cobalt, which is in good agreement with the XRF results in **Table 3**. Also, the presence of intense peaks for calcium revealed that its concentration is high, i.e., dominant element in the compound, while the lower concentration of cobalt and zinc oxides confirmed that the formed shell is so thin.

Fig. 4 SEM photos of the different wastes and the core-shell pigments.

Physical Properties of the Different Pigments

Oil absorption

Oil absorption is measured according to (ASTM D 281-12, 2016); this test gives information about the minimum amount of matrix required to wet a given weight of pigment. The results showed that both eggshells and marble possess higher oil absorption than the prepared core-shell pigments which confirms that the core-shell pigments are more economic, because less amount of oil (binder) is needed to prepare the coating film. The lower values of oil absorption can be attributed to the presence of the small plates of CoO-ZnO that overlap with the calcium carbonate rhombohedral plates or locate themselves in between them, i.e., less voids can be available for oil particles to penetrate which offers less oil absorption (Ahmed *et al.*, 2016).

Specific gravity

The specific gravity of the various materials is measured according to (ASTM D5965-02, 2013). Marble and eggshells showed high specific gravity values, while the prepared core-shell pigments offered lower values. In coatings, high specific gravity is not preferable since it can cause settling of the solid particles on storage leading to the separation of paint components. Therefore, the lower values of core-shell pigments can be considered as an advantage showing that they can be well-dispersed in the paint matrices maintaining their consistency (Table 4; Fig. 6).

Applications in Marine Paints

Corrosion studies

Corrosion protection performance of anticorrosive coatings containing CoO-ZnO/M and CoO-ZnO/ES core-shell pigments has been studied during 28 days of immersion in a chloride-containing solution (3.5% NaCl) via accelerated lab test and electrochemical impedance spectroscopy (EIS).

Fig. 5 EDAX analysis of the core-shell pigments.

Table 4 Physical properties of core-shell pigments

Pigment	Specific gravity	Oil absorption
Marble	2.52	101.1
Eggshells	2.31	91.9
CoO-ZnO/M	1.13	73.2
CoO-ZnO/ES	1.18	91.9

In accelerated lab test; the visual inspection of paint films containing the prepared core-shell pigments in Table 5 and Fig. 7 after 28 days showed that, there are no blisters on film surfaces.

The high adhesion caused by epoxy resin, leads to that no corrosion was detected under most films containing CoO-ZnO/M and CoO-ZnO/ES core-shell pigments after removing them from the steel substrates, but there was appearance of white zones that are located around X scribe (near the cut) which is related to the ability of CoO-ZnO to react with calcium

Fig. 6 Schematic diagram explaining the entrance of oil drops through core-shell pigments.

Table 5 Accelerated lab test results after 28 days in 3.5% NaCl

Formulations containing sources of calcium carbonate	Group 1		Group 2	
	CoO·ZnO/M	CoO·ZnO/ES	CoO·ZnO/M	CoO·ZnO/ES

Degree of rusting	10	10	10	10

carbonate in the aqueous media existing in marble and eggshells producing cobalt zinc carbonate hydroxide complex ($\text{CHCoO}_4\text{Zn}^+$). Additionally, the excess of ZnO which is predominant in the medium can react with calcium carbonate forming white zinc carbonate (ZnCO_3).

The action of $\text{CHCoO}_4\text{Zn}^+$ and ZnCO_3 as binding phases can fully cover the surface around X scribe making the coat more compact than the coating with only one phase of (ZnCO_3), hindering by that the penetration of H_2O , O_2 , and Cl^- to the substrate. Also $\text{CHCoO}_4\text{Zn}^+$ complex has an excellent corrosion resistance due to its high alkalinity, therefore adding pigments can improve the corrosion resistance via chemical bonding (Perez-Bernal *et al.*, 2009).

Also, ZnO itself is assumed to be able to polarize cathodic regions owing to its ability to precipitate virtually insoluble salts; depending on its reactivity and strong basicity that it can deactivate efficiently any acidic corrosion agents passing through the protective paint film. Moreover, ZnO offer good miscibility with other pigments, high covering power and ability to enhance the binder's oxypolymerization rate (Mosner *et al.*, 2000).

On the other hand, calcium carbonate which is the main constituent of both wastes can react with OH ions of water to form calcium hydroxide $\text{Ca}(\text{OH})_2$; depositing this hydroxide layer on the cathodic zones prevents corrosion of steel.

All the previous reasons combined together can explain the good corrosion protection performance of the prepared core-shell pigments. Even though, the waste materials by themselves showed less protection performance (Ahmed *et al.*, 2018).

After performing the accelerated laboratory Test, the two paint groups were subjected to electrochemical impedance spectroscopy to determine the corrosion resistance of the coatings and to confirm the results obtained from accelerated lab test. The Nyquist plots of coated plates are shown in Fig. 8 and the R_p values of the different coatings are presented in Table 6.

Fig. 7 Corrosion laboratory test results of Group I and II containing core-shell pigments in 3.5% NaCl after 28 days immersion.

Paint films containing core-shell pigments showed characteristic semicircles of capacitive type with high R_p values leading to the increase in the size of the semicircles. The results of R_p values after 28 days of immersion indicated that a common trend in the corrosion protection behavior is detected for both coatings containing the two core-shell pigments; step decrease in the electrical parameters during the first two weeks of immersion which can be attributed to the high chloride attack in this period at different areas on the steel surface. Then, gradual increase in the polarization resistance takes place due to the stabilization of the coating. After that blocking the active sites via different mechanisms offers high R_p values again after the second week of immersion.

It also can be concluded that, coatings containing CoO·ZnO/ES showed slightly higher corrosion resistance than coatings with CoO·ZnO/M. In addition, the group with higher pigment loadings exhibited higher R_p values, i.e., there is a direct relationship between the pigment loadings and the corrosion resistivity of paint films.

Mechanical properties of paint films containing core-shell pigments

The mechanical properties of paint films are represented in Fig. 9, it is clear that paint films containing CoO·ZnO/M showed high hardness values, less ductility and impact due to the marble massive particles which strengthen the paint films. While, films containing CoO·ZnO/ES showed better elasticity, i.e., less hardness but higher ductility and impact.

Fig. 8 EIS measurements of coated steel panels during 28 days in 3.5% NaCl.

Generally, the presence of CoO which is considered as intermetallic dispersoids can retard the rapid particle growth, causing particle refinement and hardening that results in further strengthening of the paint films (Fernandez and De Pablo, 2002).

Concrete Application

Corrosion studies

Fig. 10 showed the electrochemical impedance spectroscopy results for reinforced concrete containing both core-shell pigments and uncoated blank specimen, Table 7 showed the polarization resistance (R_p) values of all specimens during the immersion time.

Generally, the mechanism of corrosion in the concrete can be divided into two main phases; the “initiation phase” which includes the penetration of chloride ion through the concrete cover till the steel surface, resulting in the destruction of the formed

passive layer due to the concrete alkalinity. This passive layer is mainly composed of thermodynamically stable compounds of iron oxides and oxyhydroxides which are formed spontaneously as thin protective oxide film due to the high alkalinity of the cement hydration and free lime formation. After that, the “propagation phase” which is related to the corrosion process that starts on the rebar surface as the passive layer is destroyed. The unique composition and properties of the core-shell pigments in paint films can strongly support the protection of the reinforced bars, because of their composition which is mainly calcium carbonate and zinc and cobalt oxides that can participate in passivating and inhibiting the corrosion reaction with different mechanisms (Bertolini *et al.*, 2004).

The results of reinforced concrete steel in 3.5% NaCl solution showed that the polarization resistance values of blank specimen (uncoated) is low against the chloride attack.

On the other hand, the coated rebars with coatings containing core-shell pigments offered higher R_p values with an increasing trend due to the presence of calcium carbonate that can provide an extra alkaline medium which supports the passive layer formation around the steel, and it is considered as the first immune line against corrosive materials, This step is the one that occurs in the first two weeks, then a stability occurred between the second and third week of immersion, after that the R_p s start to increase again in the fourth week due to the destruction of the layer due to the accumulation of high chloride ions concentration which manipulates the corrosion reaction on the rebar surface. Zinc oxide is non-water soluble, thus small parts of zinc ions (Zn^{2+}) can be separated and complete the cycle of the corrosion protection mechanisms by liberating zinc ions that can reach the anodic regions on the metal surface causing a significant decrease of metal oxidation reaction and inhibit any corrosion reaction that can occur on the metal surface (Gimeno *et al.*, 2012; Li *et al.*, 2011).

Bond strength (pull out test)

From literature, it is well known that coatings cause decrease in the bond strength between concrete and the steel rebars because of their flat surface. Also, Considering the fact that coatings have some organic constituents and the main elements of concrete are inorganic, it can be supposed that the interaction between the two materials of different natures may not be as strong as if they were of the same type (e.g., inorganic). Therefore, the presence of the inorganic pigments in the coating matrix can enhance the adhesion between the coated rebars and concrete cover especially when these pigments have the capability to interact with the concrete component (Binici *et al.*, 2012).

From Fig. 11, it can be concluded that not only there was no noticeable difference between the coated specimens and blank (uncoated), i.e., the coating layer did not work as insulator between the rebar surface and concrete cover, but also the core-shell pigments which are mainly based on calcium carbonate can provide an extra calcium oxide source which can be involved in the hydration reactions of cement found in concrete cover around the coated steel. This reaction can enhance the adhesion and the strength between the rebar and the concrete overcoming the previous known deficiencies of using epoxy coatings in the field of reinforced concrete steel.

Fig. 12 represents a schematic explanation of the role of core-shell particles against corrosion in both marine paints and concrete.

Fig. 11 Bond strength (pull out test).

Fig. 12 Schematic diagram explaining the mechanism of corrosion protection in presence of core-shell particles.

Conclusions

Eggshells and marble wastes were reused as calcium carbonate derivatives that were mined from non-renewable sources. Core-shell preparation technique was applied to change the nature of these calcium carbonate sources by precipitating thin shell of CoO-ZnO binary oxide on their surfaces to study their role as anticorrosive paints in both marine paints and reinforced concrete steel. The prepared core-shell compounds were characterized using different instrumental analysis as XRD, XRF, SEM/EDAX and TEM to prove the formation of core-shell structure and determine their characteristics. Then the pigments were integrated in anticorrosive paint formulation based on epoxy resin to study their effect in protecting steel substrates in the different media. The results showed good corrosion protection in both marine and reinforced concrete applications. Beside that the prepared pigments contributed in the enhancement of the mechanical properties of paint films by providing cross-linking action between steel rebars and concrete which promoted the bond strength between coated rebars and concrete, solving a known disadvantage that is related since long time to the epoxy coatings in concrete.

Introduction

Manufacturing a wide variety of goods and products sacrifices the natural resources and contributes towards waste generation. As a result, the public and industrial communications are progressively suffering from the critical problem of wastes. Controlling the multifariousness of the waste streams is a serious challenge for decision makers and in many cases they choose inefficient and environmentally contaminating solutions such as landfill discharge (Zaman, 2015). In addition, finding suitable landfill sites is difficult and imposes a large cost (Ngoc and Schnitzer, 2009). On the other hand, improper waste management can result in unnecessary depletion of resources and loss of energy. Furthermore, many forms of pollutions such as dust, greenhouse gases, and water contamination can be raised, as illustrated in Fig. 1 (Demirbas, 2011; Udomsri et al., 2011). Therefore, adopting appropriate strategies to reduce, reuse, and recycle (known as 3R concept) the wastes is a necessity towards a sustainable development. A sustainable material flow is affected by several factors involving society, environment, design, manufacturing, recovery technology, economics, methods and usage. In this regard, the development of recovery and recycling processes can remarkably contribute to the minimization/elimination of wastes, cleaner environment, and sustainability (Kumar et al., 2005).

The aluminum manufacturing cycle releases a diversity of wastes, each of which has its own physico-chemical characteristics. The value of each waste is assessed by the amount/type of impurities and the cost of recovery (Huang and Tolaymat, 2014; Jirang and Lifeng, 2008). Among them, aluminum dross exhibits a very toxic and hazardous nature which is the main focus of the present work.

Aluminum Dross

Aluminum dross (AD) as a hazardous solid industrial waste is generated during aluminum manufacturing process. More than one million tons of AD are annually generated by aluminum sector throughout the world. Around 95% of the AD is discarded in the landfill sites (Adeosun et al., 2014). Nevertheless, according to the 3R concept, different strategies and solutions have been suggested for the reduction, reuse, and recycling of the AD. Fig. 2 shows the hierarchy of the AD.

As clearly shown in Fig. 2, the AD can be reused in the cement and concrete production. The utilization of the AD in cement mortars can result in a 15% increase in compressive strength and a 40% improvement in flexural strength. The particle size and the weight fraction of the AD were found to be very effective parameters (Dai and Apelian, 2017). It was found that the bulk density and porosity of the AD-blended cement pastes were under the effect of the amount of the incorporated AD. The former property decreased by increase of the AD replacement level in cement, while the latter one experienced an incremental trend (Inseemmesak and Rodchanarowan, 2013). Further research proved that a 5% AD replacement level improved the 7-day compressive strength of concrete (Reddy et al., 2014). This is while, a 15% AD replacement level in concrete gave the results comparable to conventional concrete (Reddy and Neeraja, 2016). Such contradictory results may be due to the different origins and chemical composition of the AD. The reuse of the AD as a refractory material is attributed to its high alumina content (Xiao et al., 2005; Yoshimura et al., 2008). The possibility of utilization of the AD in the production of zirconia/mullite composite (Castro et al., 2009), polypropylene/aluminum dross composites (Adeosun et al., 2012), epoxy resin-aluminum dross composite (Agunsoye et al., 2014), and dense multiphase β -sialon-15R ceramics (Li et al., 2012) has been reported in the literature. In the field of adsorption applications, the AD

Fig. 1 Pollution of environment by waste via different pathways.

Fig. 2 Hierarchy of aluminum dross waste.

exhibited an acceptable cadmium adsorption efficiency from aqueous solution (Ahmad Zauzi *et al.*, 2016). The reuse of the AD as a filling agent was found to be positively effective on stiffness and corrosion resistance of asphalt (Dunster *et al.*, 2005).

New technologies were also developed to reduce/minimize the generation of the AD. Oxygen-fueled rotary furnace exhibited an aluminum recycling efficiency of 80%. This type of furnace requires only 5% of energy consumed by conventional rotary salt furnace (Abdulkadir *et al.*, 2015). In Alcan plasma torch process which was implemented in Canadian Hydro-Quebec Research Center, a plasma torch was employed for heating instead of gas/oil. ECOCENT technology developed by Austrian FOCON that uses hot dross centrifuge reduces the volume of flue gas emissions, lessens adverse environmental effects, and improves energy consumption efficiency (Unlu and Drouet, 2002).

The AD contains a mixture of inorganic oxides and water-soluble salts (Mahinroosta and Allahverdi, 2018a). The water-soluble salts can be recovered through rinsing and solar evaporation. It was found that such a salt recovery has an economic benefit to aluminum industry and can diminish the toxicity of the AD waste (Bruckard and Woodcock, 2009).

As a source of aluminum, the AD powder can be utilized for the synthesis of hydrotalcites (a kind of layered double hydroxide) (Gil *et al.*, 2018), $\text{AlPO}_4\text{-5}$ molecular sieve (Murayama *et al.*, 2009; Kim *et al.*, 2009), highly crystalline CrAPO-5 molecular sieve (Kim *et al.*, 2009), Zeolite-X (Hiraki *et al.*, 2009), and sodalite and analcime zeolites (Sanchez-Hernandez *et al.*, 2016) for the application in water and wastewater treatment.

The AD is an aluminum oxide-rich waste and can be considered as a secondary resource for the production of alumina. The alumina can be recovered through acidic (Dash *et al.*, 2008; Amer, 2002; Sarker *et al.*, 2015), alkali (Lucheva *et al.*, 2005; Sultana *et al.*, 2013; Park *et al.*, 2001; Tsakiridis *et al.*, 2013), and plasma radio frequency (Yang *et al.*, 2014) routes. The objective of this work is to produce α - and γ -alumina as high value-added inorganic materials from aluminum dross using a promising recovery process. The characterization of the produced alumina products and solid residue will also be discussed.

Experimental Procedure

Materials

The AD was supplied from a domestic aluminum ingot manufacturer. The chemical reagents used in this work were: ammonia (25%, Mojallali Co.), ethanol absolute (=99% purity, Riedel-de Haën), hydrochloric acid (37%, Merck), and sodium hydroxide pellets (99% purity, Merck). Deionized water was used in preparation of solutions and washing purposes.

Alumina Recycling Process

The novel hydrometallurgy-based process and experimental conditions described in previous studies (Mahinroosta and Allahverdi, 2018b,c) were utilized to leach out alumina from the AD. In these works, a comprehensive study on the effects of leaching temperature, leaching time, acid concentration, acid-to-solid ratio, and particle size was conducted. The results revealed that the temperature leaching of 85°C, the leaching time of 120 min, the acid concentration of 5 M, the acid-to-solid ratio of 20 ml/g, and the particle size fraction of 38–75 μm led to an optimized alumina recovery efficiency of more than 80%. As typically shown in Fig. 3, in the first stage, the AD was washed with deionized water at 95°C for 90 min to remove water-soluble salts. Removing salts is essential because salts may be present in the final products as impurities.

The washed AD was then leached with 5 M HCl at 85°C for 120 min. The resulting metal chlorides liquor ($\text{pH}=3.0\text{--}3.5$) was separated from acid-insoluble solid residues using a vacuum filtration system. The metal hydroxides were co-precipitated from the chloride

Fig. 3 Production process of γ - and α -alumina from aluminum dross waste.

liquor of the previous stage by adding ammonia until the pH value reached 11.0. To separate aluminum hydroxide from other metal hydroxides, 3 N NaOH solution was added to the co-precipitates, resulting in the formation of concentrated sodium aluminate solution and undissolved metal hydroxides. Aluminum hydroxide was re-precipitated in the form of a white gel by the addition of 3 M HCl to the concentrated sodium aluminate solution. The aluminum hydroxide gel was rinsed three times with a mixture of ethanol and deionized water. The γ - and α -alumina were eventually obtained by calcination of the aluminum hydroxide at 700 and 1200°C for 2 h, respectively.

Characterization Techniques

To determine the purities of alumina products, Zn-back titration method was applied. According to this method, the obtained alumina was dissolved in a mixture of mineral acids. Then, 0.01 M EDTA was added to the resulting solution and its pH value was adjusted at 10.0 by adding a buffer solution. The pH-adjusted solution was boiled for a few minutes to accelerate the formation of Al-EDTA complex. A few drops of Eriochrome black T indicator was then added until a blue color appeared. Excess of EDTA was titrated with 0.01 M ZnSO_4 solution. The emergence of wine red color meant the endpoint of titration. The volume of the ZnSO_4 consumed in titration was used for the determination of purity. The oxide composition of the AD was obtained employing an X-ray fluorescence device (ED2000, Oxford).

Mineralogy of the AD and also the crystalline nature of the alumina products were identified employing an X-ray diffractometer (Philips Expert System, 40 kV and 30 mA). The X-ray diffractograms were recorded at 2θ range of 10° – 90° (scanning rate = $2^\circ/\text{min}$, anti-scatter = 1° ; receiving slit 0.01 mm).

A 10 kV FESEM (TESCAN MIRA3, Czech Republic) was used to investigate the microstructure of the produced alumina products. A 30 kV scanning electron microscope (SEM) device (TESCAN VEGA II, Czech Republic) was used to observe the microstructure of the AD and solid residues. The secondary electron (SE) mode of the SEM device was selected for this purpose. A 120 kV TEM (PHILIPS CM12, Netherland) was used to evaluate the morphology of the as-prepared alumina particles. To prepare the samples for the TEM analysis, they were dispersed in 5% acetic acid solution using sonication.

The infrared spectra of the alumina products were recorded by a Fourier transform infrared (FTIR) spectrometer (SHIMADZU 8400s) to identify the nature of the chemical bonds. The spectra were recorded with a sensitivity of 4 cm^{-1} and 64 scans per spectrum taken.

The surface area and porosity analyses of the produced materials were carried out by adsorption-desorption of nitrogen at 77 K with a Microtrac Bel Corp instrument (BEISORP Mini). Before any analysis, the samples were degassed at 250°C for 5 h to remove the physically-adsorbed moisture and any impurities from the materials.

Results and Discussion

Characterization of Aluminum Dross

A sieve analysis was used to assess the particle size distribution of the as-received AD. Fig. 4 shows the results.

As can be seen, around 50% of the AD particles had a size of smaller than $214\text{ }\mu\text{m}$. The inset figure indicates that the AD has a granular form with a gray-blackish color. The X-ray fluorescence (XRF) chemical composition of the AD is presented in Table 1. The data in Table 1 reveals an aluminum oxide content of more than 61 wt%, making the AD as a secondary alumina-rich resource. The AD contains more than 16 wt% silica.

The XRD pattern of the AD is depicted in Fig. 5. The results indicate that predominant mineralogical phases such as aluminum oxide, quartz, spinel, diaoyudaoite ($\text{NaAl}_{11}\text{O}_{17}$), villiaumite (NaF), cryolite (Na_3AlF_6), silicon (Si), aluminum nitride and ferric oxide exist in the AD. In addition, defect spinel ($\text{Al}_{1.83}\text{Mg}_{0.87}\text{O}_{3.61}$) and traces amounts of halite, graphite (C), and fluorite (CaF_2) were also detected.

Fig. 4 Particle size distribution of the as-received AD.

CuO	0.19

Fig. 5 XRD diffractogram of the AD.

Fig. 6 XRD patterns of (a) α -alumina and (b) γ -alumina obtained from the AD.

Characterization of Products

XRD study of crystalline structure

The XRD diffraction patterns of the obtained alumina products are shown in Fig. 6. A comparison with ICDD standard cards of 00-005-0712 and 00-013-0373 confirms the formation of α - and γ -alumina, respectively. No characteristic diffraction peaks from other impurities were identified. It is very obvious from Fig. 6 that the obtained α -alumina shows a highly crystalline nature. The line broadening in Fig. 6(b) is due to the presence of very small crystallite sizes.

The chemical transformations during the formation of α - and γ -alumina occur according to the following reactions:

Based on the alumina recovery process shown in Fig. 3, the re-precipitation of aluminum hydroxide forms an initial amorphous aluminum hydroxide (aluminum trihydroxide, $\text{Al}(\text{OH})_3$) according to reaction (1). Aluminum trihydroxide is amphoteric and plays the role of a basic species against the entrance of proton. This leads to the formation of water and aluminum oxide hydroxide ($\text{AlO}(\text{OH})$) species (reaction 2). The dehydroxylation of AlOOH at 700 and 1200°C results in the emergence of transitional gamma and the most thermodynamically stable alpha phases, respectively (reactions (3) and (4)).

The mean crystal sizes (D) of α - and γ -alumina were estimated using Debye-Scherrer equation:

$$D = k\lambda / \beta \cos\theta \quad (5)$$

where $k=0.9$, λ the wavelength of incident X-rays ($1.541874 \text{ \AA}$), θ is Bragg's angle (in degree), and β is the full width at half maximum (FWHM). The mean crystal size of α -alumina calculated from the FWHM of diffraction peak at $2\theta=43.3^\circ$ is 29.7 nm. The mean crystal size of γ -alumina using the FWHM of the peak at $2\theta=67.4^\circ$ was obtained 10.8 nm.

The Zn-back titration tests disclosed a purity of more than 98 wt% for both α - and γ -alumina products. Such a purity is high enough to use the produced α - and γ -alumina in different industrial applications.

FTIR spectroscopy

Fig. 7 indicates the FTIR spectra of the produced α - and γ -alumina ranged from wavenumbers of $400\text{--}4400 \text{ cm}^{-1}$.

The absorption band at 449 cm^{-1} belongs to pseudoboehmite structure (Cui *et al.*, 2013). The lower intensity of this band in α -alumina is due to the transformation of pseudoboehmite to alumina at higher calcination temperature. The absorption bands around 574, 852, and 862 cm^{-1} are assigned to the vibrational frequencies of aluminum in octahedral (AlO_6) and tetrahedral (AlO_4) coordinates (Li *et al.*, 2006). The typical absorption band appeared at 1004 cm^{-1} is attributed to the symmetrical bending vibration of Al-O-H . The stretching vibrations of the Al-OH bond resulted in the absorption bands at 1550 and 1558 cm^{-1} . The presence of Al-OH bands may be due to the insufficient calcination time. The band observed at 1147 cm^{-1} is as a consequence of the Al-O bond (Vasquez *et al.*, 1997). The absorption bands centered at 3535 and 3562 cm^{-1} are attributed to O-H stretching vibration of water molecules adsorbed by the alumina materials. Higher intensity of absorption band around 3500 cm^{-1} in γ -alumina is due to its higher specific surface area compared to α -alumina. The appearance of weak absorption bands at 1645 and 1649 cm^{-1} are because of O-H bending mode of physically-adsorbed water (Hariharan *et al.*, 2014).

Microstructural study

Fig. 8 shows the FESEM images of the α - and γ -alumina powders obtained from the AD. As can be observed, the γ -alumina was lumps of nanosized primary particles. The α -alumina exhibited the intense agglomerates of angular rounded-corner shaped particles.

Typical TEM observations of γ - and α -alumina are shown in Fig. 9. It can be seen that the γ -alumina particles were relatively well-dispersed and exhibited a flake-like morphology. The flakes have an average size of less than 20 nm. The observation of an individual particle of the α -alumina was very difficult. As seen from Fig. 9, the α -alumina exhibited a dense overlapped aggregates of round corner-shaped particles. The aggregates appeared to be more than 50 nm.

Nitrogen sorptometry

The surface area and porosity of the produced alumina products were measured using nitrogen gas sorptometry technique. The adsorption-desorption isotherms of nitrogen for the γ - and α -alumina were presented in Fig. 10.

According to the IUPAC sorption isotherms, the produced γ - and α -alumina exhibited the typical types IV and III curves, respectively. The hysteresis loop of type H2 indicates capillary condensation phenomenon taking place in mesopores of the

Fig. 7 FTIR spectra of (a) α -alumina and (b) γ -alumina.

Fig. 8 FESEM images of alumina products produced from the AD. Left: γ -alumina, Right: α -alumina.

Fig. 9 TEM micrographs of alumina products produced from the AD. Left: γ -alumina, Right: α -alumina.

Fig. 10 Nitrogen adsorption/desorption isotherms of (a) γ -alumina and (b) α -alumina.

γ -alumina (Čejka *et al.*, 2001). Also, the emergence of this type of the hysteresis loop reminds ink bottle-shaped pores (Sing, 1982) in the flake-like particles of the produced γ -alumina, as schematically shown in the inset figure. The specific surface area and porosity characteristics of the γ - and α -alumina are presented in Table 2. As seen, the produced γ -alumina exhibited a high specific surface area and total pore volume with a mesoporosity nature. The α -alumina was expected to exhibit a lower specific surface area and total pore volume due its very high calcination temperature, which in turn resulted in a dense microstructure as previously observed by the FESEM and TEM analyses.

Characterization of Solid Residue

The SEM analyses of the as-received AD and the acid-leached residual solids after the leaching stage are shown in Fig. 11. It is clear from Fig. 11(a) that the AD is composed of irregularly shaped particles, which have formed a relatively dense microstructure. According to Fig. 11(b), after the acid leaching stage, the dense structure has been degraded and the residual solids are composed of finer particles.

Fig. 12 illustrates a simplified schema of acid leaching of a single particle. The HCl molecules attack soluble parts and enter them into the solution phase as metal cations (M^{n+}). This causes the particle to be degraded to finer particles and eventually the morphological changes take place over acid leaching time. A diffusion-controlled mechanism was found in previous study (Mahinroosta and Allahverdi, 2018c).

Fig. 13 depicts the XRD pattern of acid-leached solid residue at the end of alumina extraction process. As seen, the predominant crystalline phase is quartz. A few amounts of aluminum oxide remain undissolved during the acid leaching stage. The inset figure clearly reveals that the solid residue experienced a color change and finer particles after the acid leaching conditions. Such detected

Table 2 Specific surface area and porosity characteristics of alumina products

Sample	Specific surface area (m^2/g)	Total pore volume (cm^3/g)	Average pore diameter (nm)
α -alumina	11	0.0487	25.16
γ -alumina	147	0.35	8.50

Fig. 11 SEM images of the (a) as-received AD and (b) acid-leached solid residue.

Fig. 12 (a) a single particle before acid leaching and (b) finer particles of solid residues after acid leaching.

Fig. 13 XRD pattern of acid-leached solid residue.

mineralogical phases suggest that the solid residue can be reused as filler/aggregate in the preparation of building and construction materials. Or it can be accumulated somewhere without any environmental pollution.

Conclusions

This research work proposed a promising hydrometallurgical process for extracting alumina from aluminum dross waste. The proposed process involved acid leaching, co-precipitation, re-dissolution, re-precipitation, washing, and calcination stages. The leaching stage as the heart of the extraction process was performed at 85°C for 120 min using 5 M HCl. The alumina was extracted in the forms of high purity (>98.0%) γ - and α -alumina, having nanostructured natures. The γ -alumina exhibited a crystal size and a high specific surface area of 10.8 nm and 147 m²/g, respectively. The crystal size and specific surface area of the produced α -alumina were 29.7 nm and 11 m²/g, respectively. The acid-leached solid residue at the end of the process had mainly a siliceous nature with a few amounts of undissolved alumina. Such a solid residue can be suitable for application in building and construction materials. Overall, the envisaged modes of utilization of aluminum dross could substantially decline the amount of aluminum dross dump, and could contribute to the sustainability of the aluminum industries and to the decrease of environmental and public health detriments.

Introduction

As a natural resource and energy-intensive industry that accounts for 7% of total CO₂ emissions, construction contributes significantly to humanity's environmental footprint. The construction materials industry, in particular fired clay-based product, concrete, and cement manufacturers, has adopted a number of measures to mitigate such adverse effects, including the use of industrial waste as aggregate or supplementary cementitious materials (SCMs) as well as recycling and reusing materials at the end of their life cycle.

That strategy is in keeping with the transition to a society in which the usability of products, materials, and resources is maintained for as long as possible and the generation of waste is minimized to create a circular, sustainable, low carbon, resource-efficient, and competitive economy. The transition underway affords Europe the opportunity to transform its economy, create jobs, and generate new and sustainable competitive advantages for the continent (European Commission, 2018). Attesting to the move in that direction is the growth in the EU's circular material use indicator for nonmetallic minerals (category MF3) from ~13.0% in 2010 to 15.2% in 2016.

Against that modern socioeconomic backdrop, one of the primary problems is the satisfactory management of industrial and construction and demolition waste (C&DW). In terms of volume, fired clay-based ceramic waste is of particular concern, as it accounts for a significant fraction (from 8% to 54%, Gálvez-Martos *et al.*, 2018) of the ~820 million tonnes of C&DW produced yearly in the EU. In that regard it is second only to concrete waste (40%–84%) and followed by other stony (unbound aggregate, asphalt) and nonstony (floating particles, glass) refuse (Medina *et al.*, 2015).

Manufacturing itself is a second source of ceramic waste, for 3%–7% of daily output is inevitably rejected, irrespective of technical improvements, translating in Europe into millions of tons per year (Tavakoli *et al.*, 2013). The percentage of wastage depends on the type of plant, product requirements, and other technical considerations.

Both red (brick and tile) and white (sanitary ware and electrical insulators) (Ogrodnik *et al.*, 2018) ceramic waste, present the world over, exhibit physical and chemical properties that depend on locally available raw materials and the manufacturing process (Siddique *et al.*, 2018). Despite those differences, all ceramic waste is durable, hard, and highly resistant to biological, chemical, and physical degradation. That notwithstanding, it is not recycled in any form at present (Binici, 2007).

Its use to manufacture concrete would enhance product sustainability, contributing to a greener environment. That, along with purely economic considerations, has created a pressing need for concrete made with nonconventional aggregates and binders bearing new SCMs.

This article discusses the key properties of tile, brick, sanitary ware, and electrical insulators and the mechanical performance of new cement matrices and recycled concretes bearing this type of waste as SCMs or coarse or fine aggregate. The most prominent scientific and technical advances forthcoming to date are addressed, based both on the worldwide literature and the many years of research conducted by the two institutions forming the SOSMAT (Spanish initials for "Construction Material Sustainability") associated research unit: The University of Extremadura and the Eduardo Torroja Institute for Construction Science.

Ceramic Waste Characterization

Chemical Composition

The literature on valorizing ceramic waste as an addition to cement or as aggregate for concrete manufacture reports as well on its chemical composition, summarized in Table 1. The data shows that all the products are acidic, comprising primarily SiO₂, Al₂O₃, and Fe₂O₃ (≥80.0 wt%) and containing smaller proportions of other oxides. The CaO content in tile, at 5.6%, in brick at 6.4%, and sanitary ware at 12.4% is much higher than the 0.76% in electrical insulators.

Sulfate, expressed as SO₃, is a minority component of ceramic waste, which is compliant with the 3.5% SO₃ ceiling set out in EN 197-1 (European Committee for Standardization, 2011a) for new cements bearing this refuse as an addition.

Ceramic Properties as Pozzolan Additions

Active additions or pozzolans are used worldwide for the economic, environmental, and technical benefits they afford. In European standard EN 197-1, naturally occurring fired pozzolans used to manufacture ordinary cement (CEM II/A and B-Q) are defined as materials "of volcanic origin, clays, shales or sedimentary rocks, activated by thermal treatment."

Table 1 Chemical composition (wt%) of ceramic waste

Oxide	Tile	Brick	Sanitary ware	Electrical insulators ^b
SiO ₂	71.89–64.20	88.40–50.91	68.41–28.86	70.9
Al ₂ O ₃	20.00–14.43	29.99–7.30	34.87–23.86	21.1
Fe ₂ O ₃	6.01–1.43	8.97–0.50	5.41–0.55	0.81
CaO	9.55–1.57	12.70–0.10	24.15–0.63	0.76
K ₂ O	2.68–1.63	4.83–0.24	3.00–1.45	3.57
Na ₂ O	3.44–2.01	1.43–0.83	2.36–1.25	1.47
MgO	3.35–0.72	4.06–0.10	2.86–0.19	3.57
SO ₃	0.0–0.06	2.54–0.20	0.07–0.00	–
LoI ^a	0.48–0.39	6.41–0.17	0.50–0.23	–

^aLoI: Loss on ignition.^bValues for the sole article published on the subject to date.**Fig. 1** (a) Relative compressive strength vs. ceramic replacement ratio by author; and (b) mean relative mechanical strength vs. replacement ratio and linear regression.

Although not initially pozzolanic, clays acquire that property when fired at 600–1000°C and ground to cement fineness. The loss of chemically combined water during calcination destroys the crystalline network of the clay constituents, rendering their components amorphous or vitreous. Pozzolanicity is therefore primarily an outcome of thermodynamic instability (Hea *et al.*, 1995). As activation temperature varies with the mineral composition of clay, it must be determined for each type of material and adjusted accordingly during firing (Calleja, 1968).

Activity can be assessed with the pozzolanicity test set out in standard EN 196-5 (European Committee for Standardization, 2011b) for the pozzolanic cements described in standard EN 197-1. Cements containing 20% ceramic waste in the form of tile and brick are standard-compliant at 28 days, the age established in earlier editions of the text (Sánchez de Rojas *et al.*, 2001). In that same vein, Lavat *et al.* (2009) found that 7- and 28-day cement bearing 30% tile passes the pozzolanicity test. Sanitary ware waste, when tested, is highly pozzolanic. Cements bearing just 10% of such waste pass the pozzolanicity test after 15 days and those with a 20% or 30% content are compliant after just 8 days, the earliest (=most demanding) age laid down in EN 197-1.

A pozzolanicity test alternative to the one recommended in EN 196-5 involves soaking the waste studied in a saturated lime solution. Trials run with that procedure showed that ceramic waste is more pozzolanic than fly ash and less than silica fume (Sánchez de Rojas *et al.*, 2006). Using the same method, Medina *et al.* (2016) observed the pozzolanicity of sanitary ware waste to be excellent, with results revealing values higher than tile and comparable to silica fume. Sanitary ware waste, then, exhibits activity similar to metakaolin, the best known and most active naturally occurring fired pozzolan (Frias *et al.*, 2000).

Most of the studies conducted explored pozzolanicity based on the mechanical strength of cement pastes, mortars, and concretes. The 28-day findings for cement-based materials bearing ceramic waste reported by different authors are graphed in Fig. 1.

The very visible scatter in the compressive strength values in Fig. 1 may be due to differences in the origin of the ceramic waste and/or in the fineness of the waste added to the cement (Liu *et al.*, 2017), which is a determinant for pozzolanicity. Despite that scatter, only one study (Oti and Kinuthia, 2016) observed relative compressive strength lower than the percentage of waste added. The evidence for waste pozzolanicity is therefore overwhelming, for in all but that case the reaction countered the reduction in cement content.

Table 2 Physical and mechanical properties of coarse and fine recycled ceramic aggregate

Property	Tile		Brick		Sanitary ware		Electrical insulators ^a	
	Coarse	Fine	Coarse	Fine	Coarse	Fine	Coarse	Fine
Sand equivalent	–	87.9–83.4	–	88.0–80.4	–	–	–	–
Density (mg/m ³)	2.4–1.9	2.6–2.1	2.4–1.4	2.5–1.9	2.6–2.2	2.8–2.4	2.3	2.5

^aValues for the sole article published on the subject to date; Coarse: Particle size fraction from 4 or 5 mm to 35 mm; Fine: Particle size fraction from 0 mm to 35 mm.

Fig. 2 Percentage variation in compressive strength of concrete vs. replacement ratio of recycled tile aggregate in (a) coarse and (b) fine aggregate.

Concrete made with cement bearing ceramic waste at small replacement ratios not only equals but improves on the mechanical strength of the reference, as observed by Kirgiz (2015) and Bediako (2018) in mortars and Letelier *et al.* (2017) and Oti and Kinuthia (2016) in concrete.

Ceramic Waste as Recycled Aggregate: Properties

The range of values found in the literature for the physical and mechanical properties of coarse and fine recycled ceramic aggregate and given in Table 2 shows that density is very similar in all four types of ceramic waste. The mean range, at 2–3 mg/m³, is lower than in natural aggregate due to the greater porosity of the waste material. The sand equivalent is similar in tile and brick and higher than 80 in both cases, an indication that as it is appropriate, the sand equivalent in clay fines has no adverse effect on the durability or mechanical strength of new concretes.

The coarse and fine aggregates made from tile and brick are much more water-absorbent than those processed from white ceramics (sanitary ware and electrical insulators). They fail to comply with the <5% recommended for conventional aggregate used in concrete manufacture due primarily to the greater porosity of red ceramics. Such high absorptivity is one of the major obstacles to their use, further to the legislation in place.

Recycled ceramic aggregate consisting of crushed brick exhibits a higher Los Angeles coefficient and crushing value than materials based on crushed tile, sanitary ware, and electrical insulators. That can be attributed primarily to the intrinsic hardness of the three latter materials afforded by the vitrification of their surface.

The Los Angeles coefficient values observed for all but the brick-based recycled ceramic aggregates lie below the 40% ceiling recommended for coarse aggregate used to manufacture concrete with characteristic strength of ≥ 25 MPa.

Performance in Recycled Ceramic Aggregate-Bearing Concrete

Compressive Strength

Further to the data in Fig. 2 that plots the percentage variation in compressive strength against the replacement ratio of recycled aggregate, the replacement of $\leq 40\%$ coarse aggregate (Fig. 2a) or 100% fine aggregate (Fig. 2b) induces no loss of compressive

Fig. 3 Percentage variation in compressive strength of concrete vs. replacement ratio for recycled brick aggregate in (a) coarse and (b) fine aggregate.

Fig. 4 Percentage variation in compressive strength of concrete vs. replacement ratio of recycled white ceramic aggregate (sanitary ware, SW; electrical insulators, EI) in (a) coarse and (b) fine aggregate.

strength. For the coarse aggregate (Fig. 2a), the variation observed at recycled waste content of 50%–100% is smaller than the replacement ratio, with values depending on the intrinsic characteristics of the tile and the water/cement ratio used in the concrete, as noted by Topcu and Canbaz (2007).

Fig. 3(a) and (b) show the effect of including different percentages of brick as coarse and fine aggregate on compressive strength relative to conventional concrete. In the former (Fig. 3a), performance declines with rising replacement ratios, except in studies conducted by Adamson *et al.* (2015) and Cachim (2009), who reported a rise in compressive strength at ratios of $\leq 50\%$. Such lower performance relative to recycled concrete containing tile or white ceramics and conventional concrete is closely related to the lower strength and higher porosity of brick-based aggregates; and their rounder shapes, that translate into weaker coarse aggregate/paste interfaces than found for aggregate with sharper edges.

Three regions can be distinguished on the graph in Fig. 3(b) for crushed brick fines. In the first, up to $\leq 15\%$, the use of the new aggregate raises compressive strength relative to the reference. In the second, for ratios of 15%–60%, no clear pattern is observed, with some authors reporting improved performance for percentages of 15%–60%, inclusive, and others decline with rising replacement ratios in the 20%–60% range. In the third, at ratios of $> 60\%$, compressive strength is observed to decline relative to the reference but by less than the replacement ratio.

Fig. 4(a) and (b) show the effect of using different percentages of white ceramics as coarse and fine aggregate on compressive strength relative to conventional concrete. Used as coarse aggregate, sanitary ware waste raises compressive strength in keeping with the replacement ratio up to 30%, due primarily to the thickness and elasticity of the new ceramic/paste interfacial transition zone (ITZ). Further to the data, electrical insulators induce a decline in performance with rising recycled aggregate content, although here also the percentage is smaller than the replacement ratio. Senthamarai *et al.* (2011), studying the effect of adding electrical insulators with different water/cement ratios, observed that at w/c of 0.40–0.45 mechanical performance was similar to that found for conventional concretes.

Fig. 5 Variation in concrete compressive strength with the simultaneous use of coarse and fine recycled aggregate (tile; brick, Br; and sanitary ware).

Table 3 Variation in tensile strength with replacement ratio by type of coarse and fine recycled aggregate

X (%)	Tile		Brick			White ceramics	
	Gr	Gr+f	Gr	f	Gr+f	Gr	f
5	↑15.0	—	—	—	—	—	—

70	—	—	—	—	↓22.5	—	—
75	↑9.7	—	↓22.2	↓5.9–↓31.3	—	—	—
80	↑3.2	—	—	—	—	—	—
100	↓3.2–↓38.5	↑3.4–↓15.6	↑4.3–↓60	↓5.0–↓52.4	↓20.9–↓37.5	↓15.5	↑36.4–↓33.9

Note: X, replacement ratio; Gr, included in coarse fraction; f, included in fines fraction Gr + f, included in both coarse and fines fractions; ↑, percentage rise relative to conventional concrete; ↓, percentage decline relative to conventional concrete.

When used as fines, white ceramics, irrespective of type, were found by most studies conducted to date to have a beneficial effect, with 60% as the optimal percentage, for performance improves less at lower and higher ratios. Nonetheless, [Alves et al. \(2014\)](#) and [Lucas et al. \(2016\)](#) reported declines relative to conventional concrete.

Fig. 5, which graphs the variation in compressive strength when recycled ceramics are used in both coarse and fine aggregates, reveals a minor decline with rising replacement ratio. The decline is lower than 15% at ratios of $\leq 50\%$ and than 25% for ratios of 50%–70% recycled brick aggregate. When 100% of the aggregate is replaced with tile waste, compressive strength rises or declines depending on the type of tile. When the aggregate is crushed brick, the decline is more intense than found for the other ceramics, ranging from 27% to 38%. Replacing conventional with recycled sanitary ware aggregate raises mechanical strength significantly.

Splitting Tensile Strength

The splitting tensile strength values of recycled concrete containing ceramic waste as (coarse, fine, or coarse+fine) recycled aggregate relative to conventional concrete are given in [Table 3](#). As [Table 3](#) shows, the use of brick as a coarse aggregate induces a

steeper decline than the use of other types of ceramic aggregate, due primarily to its higher porosity and the features of the resulting ITZ, (Sáez del Bosque *et al.*, 2017). Strength is observed to rise with tile at percentages of $\leq 35\%$ and from 60% to 80%, whereas when white ceramics are used strength grows slightly or remains practically flat at replacements of $\leq 25\%$.

When crushed brick waste is used as fines, strength rises at contents of $\leq 40\%$, while the use of white ceramics raises splitting tensile strength across the board. Alves *et al.* (2014), however, reported declines irrespective of the replacement ratio studied (20%, 50%, and 100%).

The simultaneous use of white ceramic waste in the coarse and fine fractions induces rises in strength at percentages of $\leq 20\%$. The sole paper published on 100% replacement (Elçi, 2016) shows that strength rises slightly ($\sim 3\%$) with floor tile and declines ($\sim 16\%$) with wall tile waste.

Conclusions

The conclusions drawn from this review are listed below.

- $\text{SiO}_2 + \text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3$ accounts for ≥ 80 wt% of the chemical composition of ceramic waste (tile, brick, sanitary ware, and electrical insulators).
- In terms of pozzolanicity and origin, ceramic qualifies as a naturally occurring fired pozzolan.
- A relationship is observed between compressive strength and amount of ceramic waste used. Many of the studies reviewed show that materials bearing ceramic waste exhibit compressive strength not only comparable to but higher than the reference material.
- Although recycled ceramic aggregate is less dense and has higher water absorptivity than conventional aggregate, neither fact limits its valorization in recycled concretes.
- Tile, sanitary ware, and electrical insulator waste have more suitable Los Angeles coefficient and crushing values than brick-based waste.
- Ceramic waste has a greater impact on new concrete compressive strength when used as coarse than as fine or a mix of coarse and fine aggregate.
- The beneficial effect of recycled ceramic aggregate on new concrete splitting tensile and compressive strength is approximately the same in tile and white ceramics and much smaller in brick.

Despite the research already conducted, further studies are needed for a fuller scientific/technical understanding of the effect of this type of waste on mechanical performance as well as of the resistance of new cement-based materials to aggressive environments (CO_2 , Cl^- , $\text{SO}_4^{=}$, sea water, freeze/thaw, etc.).

Recycling Aluminosilicate Industrial Wastes Into Geopolymer: A Review

Ali Allahverdi and Mostafa Mahinroosta, Iran University of Science and Technology, Tehran, Iran

Introduction

Rapid development of infrastructures in developing countries over the past several decades has made the Portland cement (PC) as the key construction material with a world demand projected to rise 4.5% per year to 5.2 billion metric tons in 2019 (Green, 2015). PC production, however, accounts for huge amounts of greenhouse gas emission, accounting to 5%–8% of total man-made CO₂ emission (Scrivener and Kirkpatrick, 2007) both directly and indirectly. Global concerns over climate change due to excessive greenhouse gas emissions along with some superior durability properties of non-Portland cements have created increasing interest in developing environmentally-friendly cements alternatives to PC. Among non-Portland cements, geopolymer cements that can be simply produced by alkali activation or geopolymerization of appropriate aluminosilicate precursors has attracted researcher's attention.

Geopolymer cements can be considered as a sub-group of alkali-activated materials that are produced by chemical activation of suitable reactive aluminosilicate materials using highly alkaline activator solutions. Alkali-activated materials have a long history dating back to the 1940s with the introduction of alkali-activated Blast furnace slag by Purdon (1940). The work on geopolymer materials, however, started later in 1970s by the work of Davidovits (1979), who activated metakaolin (MK) with soluble alkali silicate in 1975 and named the product as the first mineral resin or mineral polymer. The term 'geopolymer' was first applied in 1978 by Davidovits (2008) to introduce a new group of alkali-activated materials characterized by a three dimensional networks of aluminosilicates.

Based on definitions given by Davidovits (1991a) and Duxson *et al.* (2007a) geopolymers or inorganic polymers are a subset of alkali- activated materials possessing a disordered aluminosilicate network of a higher degree of connectivity (overwhelmingly Q⁴). Fig. 1 represents the molecular units of the molecular structure of geopolymers proposed by Davidovits (2005).

The mechanism and chemistry of geopolymerization reactions have been the subject of much scientific discussion over the past two decades showing that the mechanism and chemistry of the binder depend on the properties of both the aluminosilicate precursor material and the alkali-activator. The presence of calcium, for example, is very determinative in the mechanism and the type of binding compound being formed. In the absence of calcium or presence of low amount of which N–A–S–(H) binding compound and geopolymer material is formed (Davidovits, 1991a; Richardson *et al.*, 1994; Wang and Scrivener, 1995; Duxson *et al.*, 2007b; Bell *et al.*, 2008; Yip *et al.*, 2008). The presence of significant amounts of calcium in the reacting media, however, results in the formation of C–(A)–S–H binding compound (Richardson *et al.*, 1994; Wang and Scrivener, 1995; Yip *et al.*, 2008).

Provis *et al.* (2005a) presented a model for the geopolymerization reactions starting with dissolution of aluminosilicate source material in alkali- activator solution with a subsequent oligomerization of silicate and aluminate monomers. The formed aluminosilicate oligomers then condense into a disordered aluminosilicate gel upon polymerization. Depending on the reacting conditions, the intermediate aluminosilicate oligomers can also result in the formation of nano-crystalline zeolite phase upon nucleation and crystallisation. Fig. 2 displays the conceptual model proposed for geopolymerization (Duxson *et al.*, 2007b).

The properties of geopolymer materials greatly depend on both the composition and properties of the starting materials and the processing conditions applied. According to Davidovits (1991b), the atomic ratio of Si:Al is very determinative so that ratios lower than 3 provide rigidity to the geopolymer and ratios higher than 15 impart ductility and polymeric character to the material. Mechanical properties (Yip *et al.*, 2008; Kaps and Buchwald, 2002; Temuujin *et al.*, 2009; Škvára, 2007) resistance to acid media (Palomo *et al.*, 1999a; Shi and Stegemann, 2000; Allahverdi and Škvára, 2001a,b, 2005; Bakharev *et al.*, 2003; Pacheco-Torgal and Said, 2011; Vafaei *et al.*, 2018), resistance to high temperatures (Pawlasova and Škvára, 2007; Krivenko *et al.*, 2013; Perera and

Trautman, 2006; Kong and Sanjayan, 2008; Temuujin *et al.*, 2011; Zhao and Sanjayan, 2011), resistance to cycles of freeze-thaw (Yunsheng and Wei, 2006; Dolezal *et al.*, 2007; Bortnovsky *et al.*, 2007; Slavik *et al.*, 2008; Brooks *et al.*, 2010) are among interesting properties of geopolymer materials that received increasing interest in the literature.

Geopolymer cements can be produced either by using raw/processed aluminosilicate natural source materials such as natural pozzolans (Verdolotti *et al.*, 2008; Kani and Allahverdi, 2009; Miller *et al.*, 2010; Allahverdi *et al.*, 2011; Kani *et al.*, 2012), natural zeolites (Villa *et al.*, 2010), uncalcined/calcined clays (Zhang *et al.*, 2014), etc., or aluminosilicate industrial waste materials such as fly ash (FA) (Singh *et al.*, 2015; Zhuang *et al.*, 2016; San Nicolas *et al.*, 2017; Ma *et al.*, 2018).

A survey in 2008 reported that only 43% of total annual production of FA in the United States, which amounts to about 131 million tons, is re-used with the remaining ash piles causing increased environmental threats (Johnson, 2009). Considering the significant growth in global annual production of industrial wastes, re-use of industrial waste materials for production of geopolymer cements has provided a multifold strategy for not only considering global concerns over greenhouse gas emissions, but also targeting industrial waste management, conserving natural resources that are currently being utilized in PC production and also opportunities for development of low cost cements.

The majority of the research works on alkali-activated and geopolymer materials are focused on granulated Blast furnace slag from pig iron production process and FA as a waste residue in coal combustion process due to their worldwide availability and also their high contents of reactive silica and alumina. However, many different aluminosilicate industrial waste materials can be used as a suitable precursor for synthesis of geopolymer materials. The determining key-factor for suitability of a precursor for geopolymer production is to contain enough amounts of reactive silica and alumina that are easily dissolved in alkali activator solution that provides a high pH medium. For this reason, many attempts have been devoted to the development of geopolymer materials from aluminosilicate industrial waste materials other than FA.

This paper is devoted to a systematic review on the last decade published literature on recycling non-fly ash aluminosilicate industrial waste materials such as construction and demolition wastes, waste glass, red mud, mining tailings, etc., into geopolymer material. Granulated Blast furnace slag and other calcium silicate slags are not of concern in this study, since alkali activation of these materials results in formation of calcium silicate hydrate (C-S-H) and calcium(-sodium) aluminosilicate hydrate (C,N-(A)-S-H) as the main binding compounds compared to geopolymer materials, which are mainly composed of sodium aluminosilicate hydrate (N-A-S-(H)).

Aluminosilicate Industrial Waste Materials Used as Geopolymer Precursors

Due to potential environmental and technical advantages of geopolymer binding materials over PC, conversion of aluminosilicate industrial waste materials into geopolymer material has been considered as an appropriate solution for effective management of aluminosilicate industrial waste materials. This has motivated researchers to evaluate the potential of different aluminosilicate industrial waste materials as alternative precursor for geopolymer material. Here, we briefly review and discuss the relevant literature chronologically.

Construction and Demolition Wastes (CDW)

CDW is one of the largest waste streams generated in both advanced and developing countries and its management has become an important worldwide problem. It is defined as waste materials generated from construction projects, demolition of buildings, structures and roads and land clearing activities. CDW consists of numerous materials, including concrete, bricks, ceramic and tile, gypsum boards, glass, wood, etc., many of which have potential to be recycled. In Europe, construction sector produces 820 million tons of CDW annually that is equal to about 46% of the total waste generation according to (Eurostat, 2017). The traditional tendency for CDW disposal has been discarding it in landfills or even in open dumps. But recently, due to environmental considerations reduction, recycling and reusing strategies are emphasized. Recycling of CDW into alkali activated or geopolymer binders, therefore, is an important step towards sustainable waste management.

Allahverdi and Kani (2009, 2013) used waste brick and waste concrete powders as precursor for geopolymer. They activated waste brick and combinations of waste brick with waste concrete with alkali activators of different compositions based on sodium silicate (SS) and sodium hydroxide (SH) solutions. They reported a maximum 28-day compressive strength of about 50 MPa achieved from paste specimens. Based on their results, the mechanical properties of the prepared geopolymer samples strongly depend on the composition and reactivity of the precursor materials and optimization of both dry binder and also the activator is necessary.

CDW can be used for production of quality aggregate. In the aggregate washing stage, however, a significant amount of filter cake waste mainly composed of fine silt particles is produced that has no use and is normally landfilled. Lampris *et al.* (2009) investigated the possibility of converting filter cake of aggregate washing plant into aggregate using geopolymerization technology. 100% dried and ground silt, mixtures of silt with 20% (w/w) of silt substituted by either MK or pulverized fuel ash (PFA) were activated with an alkali activator based on SH and SS solutions. Three different curing regime including room temperature curing at 25°C for 7 days (RT), heat curing at 60°C for 3 days and then continued room curing for 4 days (RT+60) and heat curing at 105°C for 1 day were applied to paste specimens. Geopolymer paste produced from 100% silt showed an average 7-day compressive strengths of 18.7 MPa and partial replacement of silt by MK or PFA increased average compressive strengths to 30.5 and 21.9 MPa, respectively. Application of heat curing at 105°C for 1 day was beneficial and resulted in a compressive strength of 39.7 MPa. Fig. 3 depicts the positive effect of curing

Fig. 3 Effect of curing conditions on compressive strength of silt geopolymer. RT: 7 days of curing at room temperature; RT + 60: heat curing at 60°C for 3 days and then continued room curing for 4 days; 24 h at 105°C: curing for 24 h at 105°C. Reproduced from Lampris, C., Lupo, R., Cheeseman, C.R., 2009. Geopolymerisation of silt generated from construction and demolition waste washing plants. Waste Manage 29, 368–373.

temperature on compressive strength of silt geopolymer. Based on experimental results of the research, silt generated from washing plant has potential for being reused in aggregate production.

Rapazote *et al.* (2011) used tile, brick and ceramic waste (A) and concrete and stone masonry waste (B) as precursors for geopolymer mortar preparation. A 2-h thermal treatment at 750°C was applied to material B to increase its reactivity. Calcined water treatment plant sludge (material L) was also used as an alumina rich additive material. Aggregates were also prepared from the same source materials (A and B) by crushing and classification. Plain B, combination of 0.7A + 0.3L (AL) and combination of 0.35A + 0.5B + 0.15L (ALB) were activated by a proportioned mixture of SH and SS and mortar specimens with binder-to-aggregate ratio of 0.5 were prepared and cured hydrothermally at 65°C for 48 h. Based on compressive strengths of 43.8, 42.9, and 20.6 MPa for mortar specimens based on AL, ALB, and B binders, respectively, they concluded that binder B (concrete and stone masonry waste) exhibits a low mechanical performance compared to AL and ALB. They also compared the fire resistance of geopolymer mortars using OPC mortar specimens as control. The specimens were heated inside a furnace up to 900°C, kept at 900°C for 2 h, and then left inside the furnace for 1 day to cool down. Compared to OPC control mortar that was completely disintegrated with zero residual compressive strength, geopolymer mortars retained their cohesion and exhibited significant residual compressive strengths of 18.0, 11.0, and 4.8 MPa for AL, ALB, and B, respectively.

Reig *et al.* (2013) prepared cement pastes and mortars from alkali activated red clay brick that is claimed to be a major part of CDW in Spain originating from sintered red clay ceramics. The effect of different parameters including composition and concentration of alkali activator, water-to-binder (w/b) ratio, binder-to-sand (b/s) ratio on compressive strength of mortar specimens cured at 65°C at a relative humidity (RH) of 90%–95% for 3 and 7 days were investigated. Both 3- and 7-day compressive strengths increased to peak values as the SS content of activator was increased to an optimum value. Very significant increases in compressive strength was also observed water-to-binder ratio was decreased at constant activator-to-binder and $\text{SiO}_2/\text{Na}_2\text{O}$ ratios. Compressive strengths up to 50 MPa were achieved by optimizing the w/b, b/s and $\text{SiO}_2/\text{Na}_2\text{O}$ ratios. Thermogravimetric analyses results displayed the formation of zeolitic-like phases when activators of low alkaline concentration were used.

Pathak *et al.* (2014) used concrete powder and brick powder as precursor for geopolymer paste preparation using SH and SS as activator. Based on isothermal calorimetry data, they concluded that plain concrete powder is not enough reactive for geopolymerization. The effect of milling time of brick powder and the concentration of SH and SS in activator solution on compressive strength was studied. A maximum 28-day compressive strength of 11.43 MPa was achieved from paste specimens cured at 60°C for 24 h and then kept in open-air condition at room temperature ($32 \pm 3^\circ\text{C}$).

Komnitsas *et al.* (2015) investigated the effect of synthesis parameters including precursor particle size, NaOH concentration (8–14 M), and curing temperature (60–90°C) on quality of geopolymer paste specimens produced from three different types of CDW including tile, brick and concrete and cured at room temperature for about one hour and then in an oven for 7 days. Geopolymers of each CDW-group exhibiting the highest compressive strength were then evaluated for their thermal stability by heating at 400, 600, and 800°C for 60 min, freeze-thaw resistance by subjecting to weekly freeze-thaw cycles at -10°C and 60°C for two months, and structural integrity upon immersion in distilled water for 2 months. The maximum compressive strengths of 57.8, 49.5, and 13.0 MPa achieved from tile, brick and concrete waste specimens, respectively, revealed the suitability of both tile and brick waste precursors for geopolymerization reactions compared to concrete waste. Geopolymer based on tile and concrete wastes displayed the minimum and maximum mass losses of about 6 and 15 wt%, respectively, upon heating at 800°C. The structural integrity of the all the geopolymers was significantly affected by freeze-thaw cycles and more significantly by water immersion. Specimens based on brick and tile wastes exhibited compressive strength losses by about 52 and 84% after 2 months of water immersion as shown in Fig. 4.

Rakhimova *et al.* (2015) investigated the effect of partial replacement of ground granulated blast furnace slag (GGBFS) in alkali activated slag cement by red clay brick waste (RCBW) powder of different source compositions on properties alkali-activated slag cement paste and mortar. They applied two grinding methods (separate- and inter-grinding), different fineness (from 300 to 900 m^2/kg), two alkali activators (sodium carbonate and SS) and two different curing conditions including normal curing

Fig. 4 Compressive strength changes of geopolymers based on concrete (C), brick (B) and tile (T) wastes subjected to freeze-thaw cycles and water immersed for two months. Reproduced from Komnitsas, K., *et al.*, 2015. Effect of synthesis parameters on the quality of construction and demolition wastes (CDW) geopolymers. *Advanced Powder Technology* 26, 368–376.

Fig. 5 The effect of RCBW/GGBFS ratio and grinding method on 28-day compressive strength of hardened AAC pastes. Reproduced from Rakhimova, N.R., *et al.*, 2015. Alkali-activated cements and mortars based on blast furnace slag and red clay brick waste. *Materials and Design* 85, 324–331.

(room temperature at RH of about 95%) and steam curing (4 h of preset, 3 h of heating, 6 h at constant temperature of 90–95°C, and finally 3 h of cooling). The results showed that 40% replacement of GGBFS with RCBW in alkali activated mortar can increase the 28-day compressive strength by about 22.6%. The replacement level can be increased up to 60% without any compressive strength loss. The effect of SS, inter-grinding, and steam curing on enhancing compressive strength was more pronounced than sodium carbonate, separate-grinding, and normal curing, respectively. Fig. 5 depicts the effect of RCBW/GGBFS ratio and grinding method on 28-day compressive strength of hardened AAC pastes.

Vásquez *et al.* (2016) activated concrete demolition waste (CDW) with SH and its combination with SS using PC and MK as corrective materials. They prepared paste specimens cured either normally at room temperature ($25 \pm 3^\circ\text{C}$) in humidity close to 90% or thermally at 70°C for 24 h at first and then continued curing in normal conditions for their experiments. Combination of SH with SS as alkali activator was more effective than using SH alone. Geopolymer based on plain CDW exhibited relatively low compressive strength up to 25 MPa and incorporation of corrective materials showed significant impacts on enhancing compressive strength. The maximum 28-day compressive strength of about 46.4 MPa was achieved from the binary precursor incorporating 10% MK activated with an activator of optimum $\text{SiO}_2/\text{Al}_2\text{O}_3$ molar ratio of 8. Microstructural studies using XRD, SEM and FTIR spectroscopy confirmed the positive effect of corrective materials in promoting the reactivity of CDW by enhancing the dissolution of its crystalline phases in alkaline activator.

Zaharaki *et al.* (2016) investigated the feasibility of using construction and demolition (C&D) wastes including tile (T), brick (B) and concrete (C) and also red mud (R), as an industrial waste, alone or in combination with ferronickel slag (S) as precursors for alkali activation. The prepared paste specimen by activating precursors of different mix proportions with a SH and SS solution of different NaOH molarity (8, 10 and 12 M) and curing them at room temperature for 4 h, then at 80°C for 24 h, followed by normal curing at room temperature up to the age of 7 days. In addition to the effect of chemical and mineralogical phase composition on compressive strength, they also investigated the structural integrity of the paste specimens after being exposed to high temperature heating ($400\text{--}800^\circ\text{C}$). As seen in Fig. 6, alkali activated tile and brick pastes exhibited significant compressive strengths compared to alkali activated slag paste. All mixed precursors exhibited compressive strengths higher than 55 MPa with maximum values up to about 76 MPa at the optimum NaOH molarity of 10.

Alkali activated pastes based on red mud alone exhibited very low compressive strengths and incorporation of red mud into alkali activated slag resulted in significant compressive strength loss. As Fig. 7 depicts, all alkali activated pastes exposed to high temperature heating exhibited relatively high compressive strength losses (about 60% at 800°C), but pastes prepared from plain slag and combination of slag with C&D wastes (25S-30T-30B-15C) possessed residual compressive strengths close to 30 MPa that is still significant.

Zawrah *et al.* (2016) investigated geopolymer production from recycled waste fired clay bricks (G) and granulated blast-furnace slag (S). In this study, plain G and binary mixtures of G and S were activated with an alkaline solution of SH and SS and paste specimens were cured normally at room temperature up to the testing age of 90 days. Geopolymer based on plain G exhibited relatively low bulk density, high porosity, high water absorption, and low compressive strength and incorporation of S up to 60% led to significant increases in bulk density and compressive strength and considerable decreases in both porosity and water

Fig. 6 Compressive strength of alkali activated pastes produced from C&D wastes alone or in combination with ferronickel slag. Reproduced from Zaharaki, D., *et al.*, 2016. Valorization of construction and demolition (C&D) and industrial wastes through alkali activation. *Construction and Building Materials* 121, 686–693.

Fig. 7 Loss of compressive strength of selected alkali activated pastes exposed to high temperature heating for 1 h. Reproduced from Zaharaki, D., *et al.*, 2016. Valorization of construction and demolition (C&D) and industrial wastes through alkali activation. *Construction and Building Materials* 121, 686–693.

absorption. Higher addition of S (80%) resulted in crack formation and demonstrated negative effects on bulk density, porosity, water absorption, and compressive strength. The maximum 90-day compressive strength of 83 MPa was achieved for the geopolymer paste prepared from the binary mix of 40% G and 60% S.

Usha *et al.* (2016) studied the effect of synthesis parameters including SH concentration, SS-to-SH ratio, alkali activator-to-binder ratio and curing temperature on compressive strength of geopolymer mortar prepared from terracotta roof tile waste. They reported 7- and 28-day compressive strengths up to about 25 and 27 MPa, respectively, under optimum synthesis conditions including; SH molarity of 11, SS-to-SH ratio of 2.5, alkali activator-to-binder ratio of 0.8, and curing conditions of 24 h at 65°C.

Robayo-Salazar (2017) studied the possibility of utilizing recycled red clay brick waste (RCBW), concrete waste (CW) and glass waste (GW) into alkali activated building materials. The prepared precursors were activated with industrial grade SS and its combination with SS solution and OPC, as a CaO source, was used for partial replacement (less than 30% by weight) of RCBW and CW. The prepared paste specimens were cured either at 25°C or 70°C for 24 h and then at room temperature in a humid chamber with RH at about 90% to the testing age of 28 days. The selected optimum binders were then used in the form of mortar using river sand for RCBW- and CW-based binders and GW as fine aggregate for GW-based binder to prepare prototypes of precast building elements that were then evaluated for properties in accordance with Colombian technical standards. The results confirmed the positive effect of the presence of optimum amount of SS in alkali activator leading to significantly higher compressive strengths. Plain RCBW-based binder activated with SH and SS of optimum composition exhibited a maximum compressive strength of 66.56 MPa when cured at 70°C. Incorporation of 20% OPC into this binder enhanced the maximum compressive strength up to 102.59 MPa for normal curing at 25°C. Plain CW-based binder activated with optimum composition of SH+SS showed a maximum compressive strength of about 27 MPa with the application of thermal curing at 70°C. A 30% incorporation of OPC into this binder resulted in significantly higher compressive strength up to 33.69 MPa for normal curing conditions at 25°C. For the case of plain GW-based binder, the maximum compressive strength of about 57 MPa was obtained when activated

with optimum concentration of SH and cured thermally at 70°C. The type 2 I-shaped pavers fabricated from RCBW-based binder met the standard flexural strength, but the RCBW-based tile did not satisfy the requirement. Both manually prepared items, however, exhibited low permeability and high impact resistance. Non-structural blocks and tiles fabricated from CW- and GW-based binders, respectively, satisfied the minimum standard requirements.

Amin *et al.* (2017) prepared geopolymer bricks from fine ceramic dust waste collected in spray dryer cyclones in tile manufacturing process. After a calcination operation at 800°C for 2 h, the ceramic dust waste was activated with alkaline solutions proportioned with slaked lime (6, 8, and 10%), SH (0, 0.5, and 1%) and water (38, 40, and 42%). The prepared paste specimens were cured normally at room temperature for 28 days. In the next step, the formulation exhibiting the highest 28-day compressive strength (about 9 MPa) was identified (10% slaked lime, 1% SH, and 38% water) and used for preparation of brick sample for further investigations. Upon increasing curing temperature from 25 to 100°C, unusual results including significant decreases in bulk density and compressive strength along with considerable increases in cold and boiling water absorption and apparent porosity were observed. They attributed these unusual observations to probable reasons including the presence of feldspar and quartz in fine ceramic dust or using slaked lime together with SH or drying of brick sample upon curing at higher temperatures that could result in crack formation.

Guo *et al.* (2017) investigated the effect of adding waste brick powder (WBP), nano-silica, and nano-alumina on bulk density and pore structure (apparent, true, and closed porosities) of class C-FA (CFA) based geopolymer. Incorporation of 30% by weight WBP into CFA-based geopolymer, resulted in an increase of about 6.1% in bulk density, and decreases of 7.7%, 9.1%, and 10.4% in apparent, true, and closed porosities, respectively, after 28 days of curing depicting significant microstructural densification. A total incorporation of 3% by weight nano-silica and nano-alumina either individually or in combination, in addition to 30% WBP, enhanced the densification and pore refinements effects. Nano-silica, however, indicated a stronger effect than nano-alumina. Compared to control sample, the CFA-based geopolymer incorporating 30% WBP, 2% nano-silica, and 1% nano-alumina exhibited decreases by about 37.8%, 41.1%, and 44.3% in apparent, true, and closed porosities accompanied with an increase of 14.5% in bulk density after 28 days of curing.

In a recent study, Tuyan *et al.* (2018) characterized the morphology and the structure of waste clay brick Powder (WCBP)-based geopolymer of optimum composition. They firstly optimized the alkali activator composition based on combination of SH and SS from the compressive strength and cost viewpoints. The optimum formulation prepared with an activator having $\text{SiO}_2/\text{Na}_2\text{O}$ mass ratio of 1.6, containing 10% Na_2O by weight of binder, and exhibiting a maximum compressive strength of 36.2 MPa after curing at 90°C for 5 days was then studied using different characterization techniques. They concluded that the porosity of the geopolymer decreases when Na_2O content and $\text{SiO}_2/\text{Na}_2\text{O}$ ratio are increased to optimum levels. The alkali activation process weakened the intensity of the crystalline peaks present in WCBP and resulted in the formation of a thermally stable geopolymer structure upon heat treatment.

Waste Glass (WG)

It is a serious challenge to dispose million tons of waste glass generated all over the world annually. In 2005, USA, China and European Union produced 20 Mt, 32 Mt, and 33 Mt waste glass, respectively (IEA, 2007; Rashed, 2014). Waste glass disposal in landfills is not only expensive, but also because of being non-degradable is not a sustainable practice. In addition, mixed waste glasses of different colors and compositions cannot be recycled into new glass. This means that sustainable efforts are very necessary for an environmentally sound management of this waste.

Puertas *et al.* (2014) investigated the possibility of using glass waste in preparation of an alkali activator for activating blast furnace slag (BFS). They have prepared a number of alkali activators by dissolving different amounts of glass waste in a solution of $\text{NaOH}/\text{Na}_2\text{CO}_3$. These activators were then compared with water-glass and plain $\text{NaOH}/\text{Na}_2\text{CO}_3$ solution in activating BFS and preparing paste specimens cured in humid bath (99% RH) at $20 \pm 2^\circ\text{C}$ for 1, 2, 7 and 28 days. Based on mechanical, mineralogical (XRD, FTIR) and microstructural (porosimetry, NMR and SEM/EDX) measurements, they confirmed that dissolution of glass waste in $\text{NaOH}/\text{Na}_2\text{CO}_3$ solution at $\text{pH} = 13.6$ provides an alkali activator that activates BFS more effective than plain $\text{NaOH}/\text{Na}_2\text{CO}_3$ solution and forms C–A–S–H gels of similar composition and structure compared to those observed in conventional water-glass activated BFS.

Redden *et al.* (2014) investigated the feasibility of activating glass powder with NaOH solutions of different molarities (4, 6, or 8 M). The obtained results showed that NaOH -activated glass powder exhibits higher compressive strength compared to NaOH -activated class F-FA if cured at lower temperatures. The plain glass powder-based binder and the binder based on 50%–50% binary blend of glass powder and FA, however, suffered from very high compressive strength losses when exposed to moisture. This strength loss was attributed to the formation of sodium silicate as the main alkali activation product, which is soluble in water. They significantly improved the moisture stability of the glass powder/FA binary binder by partially replacing the FA content of which with MK and GGBFS as Al and Ca containing source materials, respectively.

Torres-Carrasco *et al.* (2015) proved that commercial water-glass can be substituted by WG for activating aluminosilicate precursors such as FA. They activated class F-FA with three different alkali activators including; 8 M NaOH solution, 10 M NaOH solution containing 15 wt% water-glass, and activators prepared by adding different amounts of finely ground WG to 10 M NaOH solution and stirring at $80 \pm 2^\circ\text{C}$ for 6 h. Based on mechanical properties and microstructural characteristics of paste specimens cured hydrothermally at 85°C for 20 h and then in a humid chamber (99% RH) until the testing date, they concluded that WG can

Fig. 8 Compressive strength versus curing age of FA paste specimens activated with different alkali activators. Reproduced from Torres-Carrasco, M., *et al.*, 2015. Waste glass in the geopolymer preparation. Mechanical and microstructural characterization. *Journal of Cleaner Production* 90, 397–408.

be used as an effective substitute for water-glass in preparation of geopolymer. The paste specimens activated with 10 M NaOH containing 15 wt% water-glass exhibited a 28-day compressive strength of about 37 MPa and those activated with 10 M NaOH containing WG (15 g in 100 ml) exhibited a little bit higher 28-day compressive strength with similar degree of reaction, compositional (Si/Al and Na/Al ratios) and microstructural characteristics. [Fig. 8](#) compares the effectiveness of the studied alkali activators in activating FA.

[Bobiričă *et al.* \(2015\)](#) investigated the feasibility of partially replacing FA or FA/BFS-based inorganic polymers with WG prepared from spent fluorescent lamps. Using a 30 wt% SH solution and its combination with a liquid SS ($\text{SiO}_2/\text{Na}_2\text{O}$ molar ratio of 1.25) as alkali activators and curing paste specimens hydrothermally at 60°C for 24 h, then cooling for 24 h and continuing curing at 20°C for 26 days in sealed plastic bags, they concluded that incorporation of WG into FA or FA/BFS-based inorganic polymers decreases the polymerization degree and results in significant decreases in compressive strength. They attributed this depolymerization effect and strength loss to compositional changes, specifically increase in $\text{SiO}_2/\text{Al}_2\text{O}_3$ molar ratio, caused by incorporation of WG. The negative effect of WG, however, was reduced when alkali activator contained sodium silicate. This is because sodium silicate contains significant amounts of soluble silica (oligo-siloxonates) that increase the overall polymerization degree.

[Martinez-Lopez *et al.* \(2016\)](#) activated blends of urban WG (soda lime glass)/BFS using NaOH and NaOH/ Na_2CO_3 solutions as alkali activators and studied the influence of synthesis parameters including % WG, hydrothermal curing temperature, alkaline compound ratio and wt% Na_2O on 28-day compressive strength using Taguchi statistical method. Optimum compositions at the two curing ages of 28 and 180 days were 0% WG/100% BFS and 100% WG/0% BFS, respectively. Composite formulations containing 25 and 75 wt% WG, however, exhibited interesting compressive strengths. Based on statistical analysis, the compressive strength was most affected by WG, followed by curing temperature, wt% Na_2O and alkaline compound ratio. The positive effect of WG on late age compressive strengths (later than 28 days) confirmed a different hydration kinetics for WG compared to BFS. EDS analyses confirmed hydration products of different microstructure and composition depending on the WG content.

[Wang *et al.* \(2016\)](#) used waste LCD glass as fine sand in alkali activated GGBFS. Using different combinations of SS and SH as activator, they investigated the influence of different liquid–solid ratios (0.50, 0.55, 0.60), different alkaline solutions (0.5%, 0.75%, 1%) and different replacement levels (0%, 10%, 20%) of slag by waste LCD glass on workability and 3-, 7-, and 28-day compressive strengths. The workability and compressive strength of the alkali activated GGBFS increased by increasing the alkaline solution and the replacement level.

[Novais *et al.* \(2016\)](#) incorporated WG recycled from spent fluorescent lamps into MK-based geopolymer at different levels of 12.5, 25, 37.5 and 50% by weight. They used combinations of SS solution and SH solutions of 10 and 12 M and cured the specimens in different conditions including sealed in bag/open atmosphere after one-day curing at 40°C and 65% RH. They concluded that the geopolymer properties are more influenced by replacement level and curing conditions than by NaOH molarity. The lower replacement level of 12.5 wt% increased the 28-day compressive strength of the geopolymer by about 46%, while higher replacement levels resulted in lower strengths. Open atmosphere curing showed a strong effect in preventing compressive strength losses in geopolymers containing high levels of WG. The effects of WG incorporation on compressive strength and apparent density of MK-based geopolymer is displayed in [Fig. 9](#).

Fig. 9 The effects of WG incorporation on compressive strength and apparent density of metakaolin-based geopolymer; (a) 10 M NaOH, (b) 12 M NaOH. Reproduced from Novais, R.M., *et al.*, 2016. Waste glass from end-of-life fluorescent lamps as raw material in geopolymers. *Waste Management* 52, 245–255.

Vafaei *et al.* (2017) prepared high strength geopolymer binder using WG powder as the main source material. Since WG is poor in alumina, they used three different types of calcium aluminate cements (Fondu, Secar 71, and Secar 80) for partial replacements up to 24 wt% to improve the chemical composition of the main precursor. They activated binary blends of WG/calcium aluminate cement with solutions of SS and SH of constant $\text{Na}_2\text{O}/\text{SiO}_2$ ratio of 1.5 and different Na_2O contents (8, 10, 12% by weight of dry binder). Based on mortar specimens cured hydrothermally at 95°C for 20 h in a humid chamber (more than 95% RH) after 24 h of precuring in humid chamber at $23.0 \pm 2.0^\circ\text{C}$, they achieved compressive strengths up to 87 MPa. The results confirmed that inclusion of reactive alumina from calcium aluminate cements into silica-rich waste-glass causes more cross-linking in the molecular structure of the geopolymer and therefore greatly enhances the mechanical properties (up to 6 times) and reduces the tendency for formation of efflorescence. Among the three calcium aluminate cements used, Secar 71 was more effective in strength enhancement and efflorescence reduction due to its relatively higher reactive alumina content.

Fig. 10 depicts the influence of calcium aluminate cement incorporation on compressive strength of WG-based geopolymer mortar prepared at different Na_2O contents of activator.

Al Saadi *et al.* (2017) prepared inorganic binder exhibiting intumescent behavior (i.e., expansion upon exposure to high temperature) by activating WG powder derived from cullet of different colors with borax ($\text{Na}_2\text{B}_4\text{O}_7$) containing SH solution. They cured paste specimens in an oven at 60°C for 24 h and then in open air at 20°C for 7 days before high temperature treatment (1 h at different temperatures of 500, 600, 650, 700, 850°C). The results showed that incorporation of borax into SH solution lowers the intumescent temperature from 850°C to about 600°C . A 10% by weight replacement of WG with FA did not substantially affected the intumescent behavior of the material, but improved its moisture stability.

Torres-Carrasco *et al.* (2017) investigated the possibility of activating WG powder with different alkali activators. They activated glass powder prepared from waste soda-lime-silica glass of different colors with NaOH, KOH, water-glass, $\text{NaOH}/\text{Na}_2\text{CO}_3$ solutions and also NaOH and $\text{NaOH}/\text{Na}_2\text{CO}_3$ solutions in which a given amount of glass powder was dissolved at 85°C for 6 h. The paste specimens were then cured at 85°C for 20 h either at 99% or 6.5% controlled RH. The results showed that activators of higher concentrations resulted in the formation of less porous microstructures of higher compressive strengths. Curing at lower RH

Fig. 10 Influence of calcium aluminate cement (CAC) incorporation on compressive strength of WG-based geopolymer mortar prepared at different Na₂O contents of activator. Reproduced from Vafaei, M., *et al.*, 2017. High strength geopolymer binder based on waste glass powder. *Advanced Powder Technology* 28, 215–222.

of 6.5% was also more effective in compressive strength development and 50%–75% higher compressive strengths were achieved. The activation product was a silica-rich gel irrespective of the activator type or curing condition.

Wang *et al.* (2017) incorporated waste LCD glass as sand into alkali activated GGBFS at different replacement levels (0%, 20%, and 40%) and evaluated engineering properties of the mortar at different liquid-solid ratios (0.45, 0.50, 0.55, and 0.60) considering the ratio of Na₂O equivalent to the weight of GGBFS in SH solution constant at 1%. A combination of 5 N NaOH and SS was used as alkali activator and specimens were cured for one day in the molds and then at room temperature. A 20% replacement of GGBFS with LCD glass sand resulted in higher compressive strengths, but higher replacement levels had a negative effect on compressive strength. The sulfate resistance of mortar was maximized at L/S=0.6 and replacement level of 20%. The results confirmed that engineering properties of alkali activated GGBFS can be enhanced if an optimum amount of LCD glass sand is incorporated.

El-Naggar *et al.* (2017) utilized WG in preparation of MK-based geopolymer. The WG fused with NaOH pellets at 550°C was dissolved in water to prepare an alkaline solution for activating MK. Fumed silica was also added to the alkaline solution to control SiO₂/Na₂O ratio at four different levels (1.25, 1.35, 1.45 and 1.55). An alkaline solution was also prepared from reagent grade SS and SH for comparison purposes. The undissolved portion of fused WG was also incorporated into MK to see its effect on compressive strength. The effects of MK particle size, solid/liquid ratios, undissolved WG content and particle size, alkaline silicate solutions prepared from dissolution of fused WG and fumed silica, curing temperature (25, 40, 60, and 80°C) in a 2-h precuring stage and curing time on compressive strength of geopolymer were studied. MK and undissolved WG particle size and precuring stage temperature were found to be the most influential factors on compressive strength. Enhanced 28-day compressive strength of 80.75, 82.36, 93.08 and 97.41 MPa were achieved by reducing MK particle size from less than 125 µm to less than 38 µm, incorporation of 3% undissolved WG into MK, using an alkaline silicate solution containing 7% dissolved WG at SiO₂/Na₂O of 1.55, and precuring at curing at 40°C, respectively.

Zhang *et al.* (2017) investigated the possibility of using WG powder as partial replacement (10%, 20%, and 30%) of coal FA in alkali activated FA (50%)/GGBFS (50%). A 4 M NaOH solution was used as alkali activator and paste specimens sealed with plastic foil were cured at 20°C in a humid room (≥98% RH). Based on calorimetry and TG analyses, WG is more reactive than FA and incorporation of 30% WG increased 28-day compressive strength by about 35%. This effect is attributed to the high reactive contents of SiO₂ and CaO in WG and also its finer particle size compared to FA. The main alkali activation product was found to be a C-(N)-A-S-H type gel and no N-A-S-H type gel was found.

Tho-In *et al.* (2018) recycled WG powder from fluorescent lamp and ground container into high calcium FA-based geopolymer at different replacement levels of 10%, 20%, 30%, and 40% by weight. A mixture of SS and SH (1:1) was used as alkali activator and after a 1-h precuring at 23–25°C, the plastic wrapped paste specimens were cured at 60 ± 2°C for 48 h and then held at 23 ± 2°C until the testing age of 7 days. Incorporation of WG powder from fluorescent lamp was found to have a negative effect on compressive strength, while 20% replacement of FA with WG powder from container glass resulted in a 7-day compressive strength (47.6 MPa) that was slightly higher than that of reference paste (45.7 MPa).

Zhang and Yue (2018) investigated the influence of WG powder prepared from cullet of various colors from a recycling facility on flexural and compressive strengths, drying shrinkage and sulfate resistance of alkali activated slag mortar. Using a mixture of SS and SH (SiO₂/Na₂O=1) as alkali activator and applying central composite design and response surface methodology, they optimized the alkali content (Na₂O equivalent) and the replacement level based on maximum flexural and compressive strengths. Ordinary Portland cement (OPC, CEM I 42.5R) mortar specimens were also prepared and used as reference. The effect of alkali content was found to be more significant than replacement level. The optimum alkali content and replacement level of 8.31% and

14.57%, respectively, resulted in maximum 28-day flexural and compressive strengths of 8.4 and 66.4 MPa, respectively. These optimum values reduced the amount of dry shrinkage by 15.8% and 20.3% at 1 and 120 days, respectively and the sulfate resistance of the mortar. Alkali activated slag mortar exhibited higher mechanical properties, excellent sulfate resistance, and higher drying shrinkage compared to OPC mortar.

Lu and Poon (2018) studied the effects of simultaneous incorporation of WG bottle (soda lime glass) powder and fine aggregate on workability, flexural and compressive strengths, and fire resistance of alkali activated FA-GGBFS mortar. A binary blend of FA (30%)/GGBFS (70%) was used as control and natural fine aggregate was replaced with fine WG cullet at different levels of 0, 25%, 50%, 75%, 100%. In the mortar containing 100% WG cullet as aggregate, once FA was fully replaced with WG powder (30%) and once 30% of GGBFS was replaced by WG powder. A 10 M NaOH solution was used as alkali activator and mortar specimens were cured in normal condition of $25 \pm 2^\circ\text{C}$ and $50 \pm 5\%$ RH after 24 h in molds. Replacement of natural fine aggregate with fine WG cullet improved the mortar workability. The mortar workability, however, reduced by replacing FA with WG powder, and slightly changed when GGBFS was replaced with WG powder. WG cullet had a negative effect on compressive strength, but flexural strength was increased up to 50% replacement and then decreased at higher replacement levels. Incorporation of WG powder to replace FA and GGBFS reduced the compressive strength of mortar significantly. This negative effect of WG powder was attributed to its low reactivity compared to FA and GGBFS. Fire resistance of alkali activated cement mortars is usually reported to be better than that of OPC mortar. This property, however, was further improved by incorporation of both WG powder and WG cullet into the studied alkali activated cement mortar in this study.

Red Mud (RM)

RM is an aluminosilicate industrial waste produced in the production process of alumina from bauxite ore, the Bayer process. Disposal of RM in huge holding ponds without any treatment has led to a global environmental crisis due to its large production volume, high alkalinity and small particle size. It is estimated that each year approximately 120 Mt of RM is added to the existing stockpiles worldwide with an estimated total amount of 4 billion tons in 2015 (Zhu *et al.*, 2015). To alleviate the pressure from this worldwide crisis, many research efforts have been devoted to the development of sustainable RM recycling technologies.
